If we accept the view that the Earth's atmosphere has accumulated by gradual degassing of the crust, we must suppose that the Earth was originally devoid of atmosphere. In this case, the Earth's albedo would have been low initially, increasing gradually as a thin atmosphere formed. Taking 0·15 as a representative figure for the albedo of the early Earth, we can estimate from solar model calculations[1] that the average initial surface temperature of the Earth would be about 245 K. On the other hand, the local midday temperature might have been as much as 100° higher than this. As a result, any water vapour degassed would be predominantly frozen out on the surface, though local heating would return some to the atmosphere. (In the initial stages of atmospheric development the pressure would, of course, be too low for the formation of liquid water.)

This estimate of the surface temperature supposes, however, that the atmospheric gases contributed no greenhouse effect. Whether this is true or not will depend on their composition. There are two possibilities here. The first is that from early on some of the compounds degassed were oxidized (in particular, that an appreciable amount of carbon dioxide was present). The second is that the compounds were originally all reduced (methane and ammonia being especially important).

It is well known that carbon dioxide in sufficient quantity can produce a marked greenhouse effect. A rough calculation suggests, in fact, that a maximum of 200 g cm^{-2} of atmospheric carbon dioxide would be required to raise the average surface temperature of the Earth from the initial value of 245 K to above the freezing point of water. This estimate supposes, however, that the carbon dioxide acts alone; but actually, as the temperature rises, so the amount of water vapour in the atmosphere will also increase. Water vapour is an efficient infrared absorber, but has a window in the 9–18 μm region where the terrestrial radiation peaks. Carbon dioxide, on the other hand, has a main absorption band in this region. The result is that the two gases acting together produce an enhanced greenhouse effect as compared with either acting alone. Hence the figure quoted for the required amount of carbon dioxide is a considerable over-estimate; after all, the present Earth has a greenhouse effect $\sim 35^\circ$ with only 0·5 g cm^{-2} of carbon dioxide.

If we turn now to the comparable situation in a reducing atmosphere, we find that ammonia also absorbs within the water vapour window. Hence a combination of ammonia and water vapour, like carbon dioxide and water vapour, would produce an appreciable greenhouse effect. A reducing atmosphere could therefore raise the surface temperature of the early Earth in the same way as an oxidizing atmosphere. The difference is that ammonia is much more soluble than carbon dioxide in water. As a result, any extensive formation of liquid water on the Earth's surface would lead to a rapid removal of almost all atmospheric ammonia. If we suppose that all the nitrogen currently present in the atmosphere and sediments has been derived from degassed ammonia (obviously an upper limit), and that all the water vapour which has been degassed is now collected in the oceans (a lower limit), then the ratio of degassed ammonia to water vapour is certainly less than 1 per cent. This is insufficient to depress the freezing point of water by any great amount. Thus, the removal of ammonia from a reducing atmosphere by solution in water would lead to a loss of the greenhouse effect and to a refreezing of the water. (In fact, there is no need for the water ever to be present as such—ammonia can be absorbed directly by ice[2].) Hence a reducing atmosphere would keep the Earth's temperature constant at, or below, the freezing point of water.

From the amount of carbon dioxide currently present in carbonate deposits, it might be expected that a carbon dioxide atmosphere would accumulate around the Earth rapidly. For example, if carbon dioxide accumulated at a steady rate, the figure of 200 g cm^{-2} would be reached in $\sim 10^7$ yr. It follows from the foregoing argument that, with a carbon dioxide atmosphere, liquid water should have appeared on the Earth's surface very early in its history. This should not be true for a reducing atmosphere. One possible method of checking on the chemical composition of the early atmosphere, therefore, is by examining the early geological record for effects attributable to water. An oxidizing atmosphere should produce indications of erosive activity, whereas a reducing atmosphere should not.

In fact, some of the oldest rocks known include metamorphosed sediments. It follows that there must have been active erosion well before $3 \cdot 5 \times 10^9$ yr ago. The Earth should have had an oxidizing atmosphere for at least this length of time.

There are two points to be noted about this argument. The first is that, if liquid water is created in the presence of excess carbon dioxide, it might be expected that some of the latter would be removed by the Urey reaction[3]. Not only would this reduce the greenhouse effect, but the resultant SiO_2 deposits might be expected to appear in the geological record. It is certainly true that the growing oceans would stabilize the amount of atmospheric carbon dioxide. As long as the early oceans had the same character as the present ones, however, an adequate greenhouse effect would be produced by the carbon dioxide remaining in the atmosphere. As far as the deposition of SiO_2 is concerned, it must be remembered that the Urey reaction is really a symbolic representation of a more complex series of processes, some of which would certainly have gone more slowly on the primitive Earth. The situation seems to be that only partial pressures of carbon dioxide equivalent to one atmosphere pressure, or more, can be ruled out.

The second point to note, however, is that the complex buffering system of the oceans with respect to carbon dioxide, and, ultimately, the Urey reaction, do act as a control on the amount of carbon dioxide in the atmosphere. The presence of liquid water on Earth thus limits the extent of the greenhouse effect. It has been supposed in the foregoing discussion that the Earth degassed at a uniform rate. This, however, is rather improbable; it is much more likely that the initial emission of gases occurred more rapidly[4]. In this case, if a large amount of carbon dioxide degassed in the initial burst, the resulting greenhouse effect might produce a surface temperature which immediately exceeded the boiling point of water. With no liquid water present, there would be no mechanism capable of removing carbon dioxide rapidly from the atmosphere. The surface temperature would remain high, and no oceans would form. This has obviously not occurred on Earth, but it may describe what happened on Venus, where, in any case, the initial surface temperature must have been $\sim 50°$ higher due to the greater proximity of the planet to the Sun.

I thank several of my colleagues in the Geology Department for their advice on various aspects of this work.

New Model for the Structure of the Ocean Crust

Using the ocean floor spreading/plate tectonics theory as a starting point, examining the implications of this theory for processes taking place at mid-ocean ridge crests, and adding data collected from dredged rocks and geophysical measurements in the oceans, it is possible to build up a well controlled model of the structure of the ocean crust and the way in which it is formed.

Studies of magnetic anomalies[1,2] and earthquake fault plane solutions[3,4] have shown that the mid-ocean ridges are lines along which plates of the lithosphere are moving apart. During this movement, upper mantle material rises as a hot diapiric intrusion from the mobile asthenosphere to fill the crack between the plates. Material from within the asthenosphere will be hot enough, if it rises fast and cools essentially adiabatically, to pass through the basalt melting curve and form an interstitial basaltic melt[5]. (This is not to imply that an interstitial melt is not present in the asthenosphere, but only that its composition is not basaltic.) The formation of such a basaltic interstitial liquid is demonstrated by the eruption of basalt lavas all along the crests of the mid-ocean ridges. Evidence from magnetic anomalies[6,7] and petrography[8] shows that the zone of eruption of lavas is very narrow, certainly less than 25 km wide, and perhaps in places as narrow as 0·5 km. This basaltic material must form at least a large part of the ocean crust[5], and the formation of new crust must thus be confined to a narrow strip along the mid-ocean ridge crests.

It is important in this analysis that the incoming mantle material must rise fast from 100–200 km depth along a narrow zone. Thus the widening crack between the lithospheric plates must be narrow and nearly vertically sided. Models with gently sloping sides to the lithospheric crack, attractive on other grounds because of the lower velocity necessary in the rising mantle, do not seem to fit the requirements of melting and eruption (Fig. 1).

What, then, accounts for the transition on the walls of the crack from mobile asthenospheric material to rigid lithospheric material? In such a vertical-sided crack, the explanation cannot be, as it could be in a crack with a tent-like shape, the cooling of the rising material by conduction through some temperature interval separating plastic from rigid behaviour. Rather it must be that the mobile behaviour is associated with interstitial liquid, which not only lubricates grain contacts but acts as an ionic carrier during the recrystallization that must accompany flow. Thus as the mantle material rises it flows more and more readily because the amount of interstitial liquid increases with progressive melting. When the liquid has increased in volume enough to leave its parent material and rise further towards the surface, however, the ability of the parent material to flow is drastically reduced, and it becomes at this stage part of the lithosphere.

Although much of the rising asthenosphere loses its liquid at some depth in the crack, part at least of the material must retain its interstitial liquid while it flows to near the top of the crack in the lithosphere to form the mantle immediately beneath the Mohorovičić discontinuity. To reach this position the material must have retained its high temperature or the interstitial liquid would solidify and increase the rigidity of the rising diapir. Thus the temperature at the level of the top of the mantle must be at about the melting point of basaltic magma (*c.* 1,100° C). Basaltic liquid rising from lower in the crack through this zone will not solidify there, but will accumulate as a pool of liquid overlaying the top of the column of asthenospheric material filling the crack. Thus, along the crestal zone of the mid-ocean ridge system, the lower part of the oceanic crust should consist of a magma chamber filled with basaltic liquid (Fig. 2).

Dredging from the crests of mid-ocean ridges shows that the basaltic liquid is usually erupted in the form of pillow lavas (sometimes it is found as thin ropy lava flows). The pillows form steep-sided hills, mushroom-shaped in cross-section, elongated parallel to the mid-ocean ridge axis. These hills form a capping on the vertical dykes that feed them. As cracking of the lithospheric plate continues, further eruptions of pillow piles take place, overlapping and building up on earlier ones, so that an upper crustal section of piled-up overlapping mushrooms develops.

In an earlier examination of processes at mid-ocean ridge crests[5], it was assumed that this piling up process continued until the whole ocean crust was composed of superimposed pillow lava piles. This is not, however, tenable, as no model can be constructed in which a pillow pile, originally at the top of the crust, becomes buried until it lies in contact with the mantle. Only a limited amount of burial can take place in practice, resulting in an upper skin to the crust of piled up pillow lavas. The thickness of this skin will depend on the ratio of extruded lava to that remaining in the dykes.

Beneath this skin is a zone made of basalt that has never reached the surface. This takes the form of a dense complex of feeder dykes, intruding each other and following the gaps between previous dykes, as was envisaged in the original models for magnetic anomalies[6,10]. These dykes rise from the magma chamber at the base of the crust. Near the magma chamber, where the ambient temperature is high and the rate of cooling slow, they will crystallize to coarse-grained rocks. Higher up, the rate of cooling will be faster and the grain-size correspondingly less, giving rise to basalts and dolerites.

In the active crestal zones of the mid-ocean ridges the crust consists of a layer of pillow lava units fed by dykes overlying a zone of dykes without lavas, which become coarser-grained downward towards a basaltic magma chamber at the base of the crust (Fig. 2).

Three metamorphic facies have been recognized in rocks from the ocean floor, a facies in which clay minerals develop from ferro-magnesian minerals of basalts[11], a greenschist facies[11,12], and a facies in which green hornblende replaces basaltic ferro-magnesian minerals[13]. The first two facies indicate the presence of abundant water during metamorphism, but the third, in which plagioclase shows no sign of reaction to more sodic compositions with the formation of epidote, apparently represents a higher temperature, but water deficient, environment.

Water in the ocean crust has two sources: sea water trapped in the cavities within and between the lava pillows as they form, and water from cooling and crystallizing basaltic liquids. Because of the low water content of basaltic liquids, the second source must be much less important than the first, and metamorphism within the layer of pillow lavas will take place under much more water rich conditions than within the complex of dykes that underlies it. The first two facies can thus be assigned to the pillow lava layer of the crust, and the third to the dyke swarm.

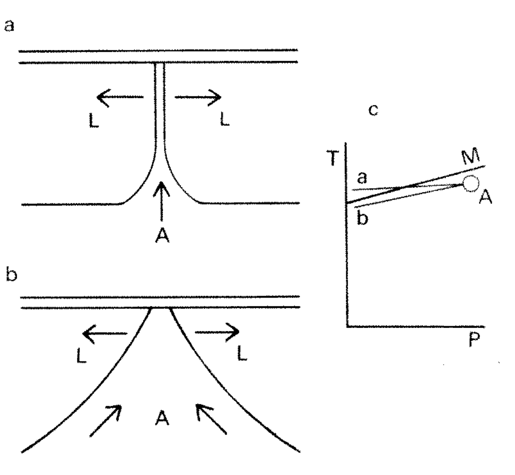

Fig. 1. L, Lithosphere; A, asthenosphere. *a* and *b*, Alternative models showing the lithospheric crack with vertical and sloping sides. *c*, Schematic P–T diagram showing how mantle material rising vertically (as in model *a*) from the asthenosphere (A) crosses the basalt melting curve (M) while mantle material rising slowly (as in model *b*) cools by conduction and does not cross the basalt melting curve.

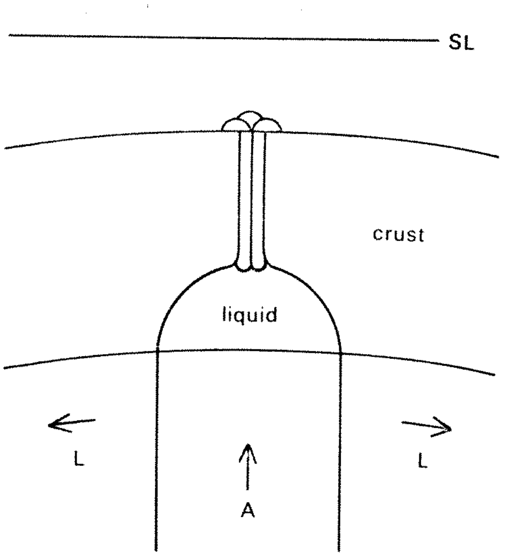

Fig. 2. L, Lithosphere; A, asthenosphere. An enlarged view of the crust and the top of the rising column under mid-ocean ridge crests, showing the active structures.

As the ocean crust migrates away from the ridge crest down the flanks of the ridge, some modifications of the structure in the active zone take place. First, the liquid magma chamber at the base of the crust slowly solidifies, losing its heat by conduction through the overlying ocean crust. During this process fractional crystallization will take place, with the formation of layered gabbros on the floor of the chamber, and with the production of the granitic or dioritic late differentiates that have recently been dredged from the oceans[14,15]. Water released during crystallization may help to cause localized metamorphism of the gabbros themselves[13], but some must also react with the underlying mantle, as the temperature falls, to form serpentinite. Because of its low density, this serpentinite will intrude upwards as diapiric masses through the ocean crust[13], giving rise to the serpentinites that have been dredged from the ocean floor.

The final crustal structure envisaged is shown in a somewhat diagrammatic form in Fig. 3 (the normal faults cutting the ocean crust have been omitted for clarity).

A zone of unmetamorphosed pillow lavas overlies metamorphosed pillow lavas in two zones. These are intruded by feeder dykes for the flows. Beneath this is the dyke swarm proper (mostly metamorphosed to the hornblende-bearing facies) which grades downwards through coarser-grained dykes to a massive layered gabbro forming the lower crust. Serpentinite diapirs from the uppermost part of the upper mantle intrude through this complex.

The most important consequence of this model is the postulated presence of a liquid lower crust along the length of the axial zone of the mid-ocean ridge system. The presence of this feature should be detectable by seismic or magneto-telluric means. The boundary between seismic layers 2 and 3 in the ocean crust is interpreted here as the junction between the zone of pillow lavas, metamorphosed in part, and the underlying more massive dyke swarm and gabbro, while the Mohorovičić discontinuity is the boundary between gabbro and peridotite. The heat flow at mid-ocean ridge crests is, in the model, controlled by the presence of the basaltic magma chamber in the lower crust. Assuming a depth to the top of this chamber of 4 km below the ocean floor, a temperature

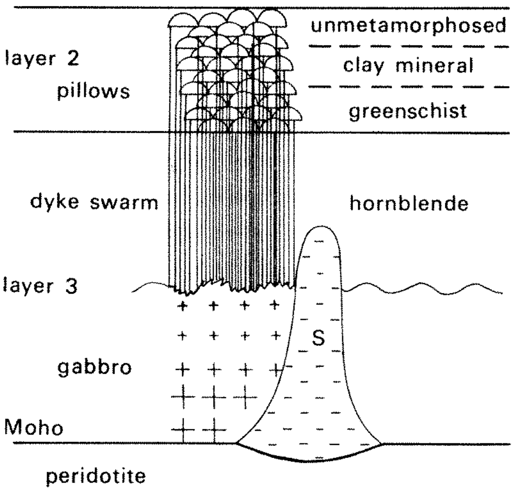

Fig. 3. Section through the ocean crust as envisaged by this model. S is a serpentinite diapir.

within the chamber of 1,100° C, and thermal conductivity of the overlying rocks as 4×10^{-3} calories^{-1} s^{1} degree^{-1}, a heat flow of 10×10^{-6} calories cm^{-2} s^{-1} may be calculated. This is within but at the upper limit of values measured near ridge crests. This agreement is satisfactory. Agreement with magnetic models of ocean crust structure is also satisfactory. Magnetic rocks will be found in the upper parts of the zone of pillows and in the dyke swarm metamorphosed under water deficient conditions. The layered gabbro composing the lower crust would be expected to be essentially non-magnetic, as would also be the basalts metamorphosed in the greenschist facies.

The model has been constructed entirely from the consequences of the plate tectonics theory and from consideration of the rocks and geophysical measurements from mid-ocean ridges. No reference was made, or was necessary, to the ophiolite complexes seen on the continents, which many people interpret as slices of ocean crust thrust in among continental rocks during mountain building[16,17]. When comparison is made between the model and the observed structure of ophiolite complexes, such as the Troodos complex in Cyprus[17] and the South Oman complex in Arabia[18], the similarities are consequently very striking. Both of these ophiolite complexes can be interpreted as consisting of exactly the same elements as the model, gabbro overlying peridotite and itself overlain by an intense dyke swarm, which in turn is capped by a layer of pillows.

The fact that complexes very like the model exist reinforces both the model and the interpretation of ophiolite complexes as pieces of ocean crust. Reference to the structure of the ophiolites enables refinements to be made to the model, for example that the contact of the gabbros with the peridotites is rather complex, with gabbro dykes in the peridotite and peridotite xenoliths in the gabbros. This contact zone was measured as about 500 m thick in the South Oman complex[18], a thickness compatible with geophysical observations of the oceanic Mohorovičić discontinuity. On the other hand, reference to the model allows interpretation of features seen in ophiolite belts. The association of gabbro with peridotite can be seen to be genetic, and the association is explained. In addition, the recognition that the sub-oceanic Mohorovičić discontinuity outcrops in ophiolite belts allows this boundary to be studied without the need for expensive drilling operations.

I thank the Sedgwick Club for stimulating me to think along these lines.

Sub-Sea Floor Structure south of France

It has been suggested[1,2] that the Ligurian Sea was formed by the Corsica–Sardinia block drifting away from the south of Provence, during the Oligocene or the Miocene. These suggestions take no account of sub-sea floor structures.

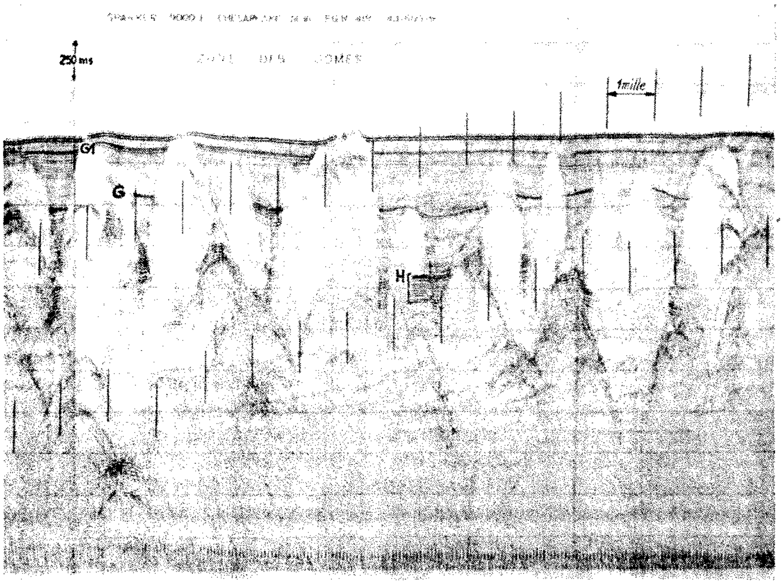

Fig. 1. *H* reflector in *A* zone: this reflector appears as a sequence of about 250 ms lying about 1 s (± 200 ms) below the sea bottom (water depth = 2,600 m). *N.B.* All times are double way times. All sections E.G. & G. sparker 9,000 J, Chesapeake M-16 hydrophone and PGR Alden 419 or E.G. & G. 254 recorders. Ship's velocity was about 6 knots—vertical scale, between scale lines 1 second on E.G. & G. 254 and 250 ms on PGR Alden 419.

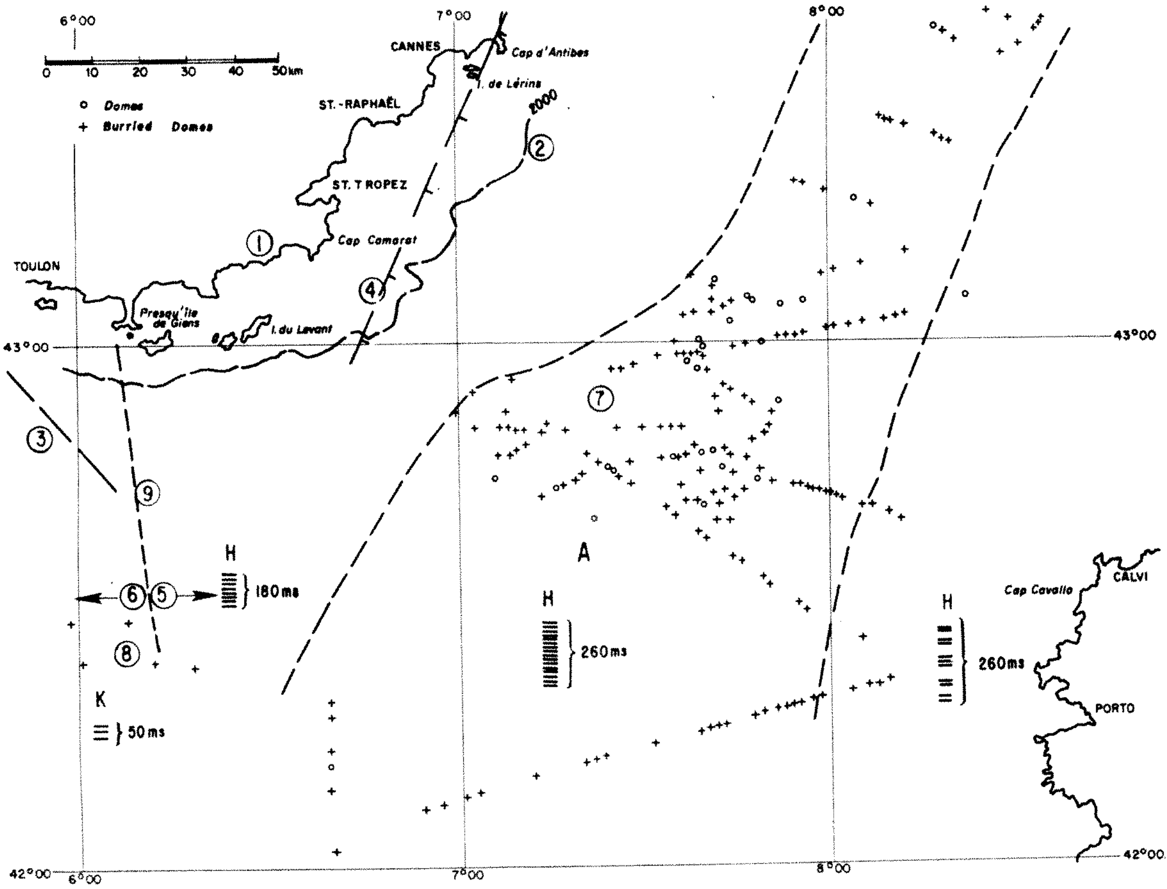

Fig. 2. Geographical distribution of the reflectors with the major accidents of the region: 1, coast line; 2, slope; 3–4, probable extension of Arles and Antibes faults; 5, presence of *H*, and 6, *K* reflexion's areas; 7, a zone with typical salt domes; 8, domes found south of Toulon; 9, zone of complicated tectonics. No reflectors can be followed for more than a few miles.

The deepest reflector in the north-west Mediterranean, as shown by continuous seismic profiling in the *A* zone of Glangeaud[3], is the *H* level[3]. This seems to be more a sequence of reflexions than a single response[5] (Figs. 1 and 2). Its character changes east of the *A* zone, where the domes become smaller and thinner[6] and disappear towards Corsica. Westward, out of the *A* zone, it shows numerous diffraction patterns. South of Saint-Tropez, this *H* level becomes shallower, and erosion patterns can be seen near the continental slope where a deeper reflector, *D*, can be traced (Fig. 3). South of Toulon, we found domes[7] larger than those of the *A* zone and comparable with the Sigsbee knolls[8] (Fig. 4).

The deepest reflector west of the *A* zone is called the *K* level[5]. Its depth is about the same as the *H* level, but it is distinctly different in character (Fig. 5), although the sedimentary section presents the same features. The southern extension of those horizons is not yet well established. Their geographical distribution is schematically shown in Fig. 2.

The various characters of the deep reflector which lies below the abyssal plain south of France seem to be related to the different palaeogeographic areas. A first interpretation has been given by Glangeaud[9]. Fahlquist and Hersey[10] computed a layer with a compressional velocity greater than 4 km/s, about 1·5 km below the abyssal plain. Should this be interpreted as a salt bed or is it connected to the magnetic basement which has been found by a local study at about the same depth[11]? There are, as yet, insufficient data to lead to a certain conclusion, but we may correlate Fahlquist's layer with the reflector *D* (see Fig. 3).

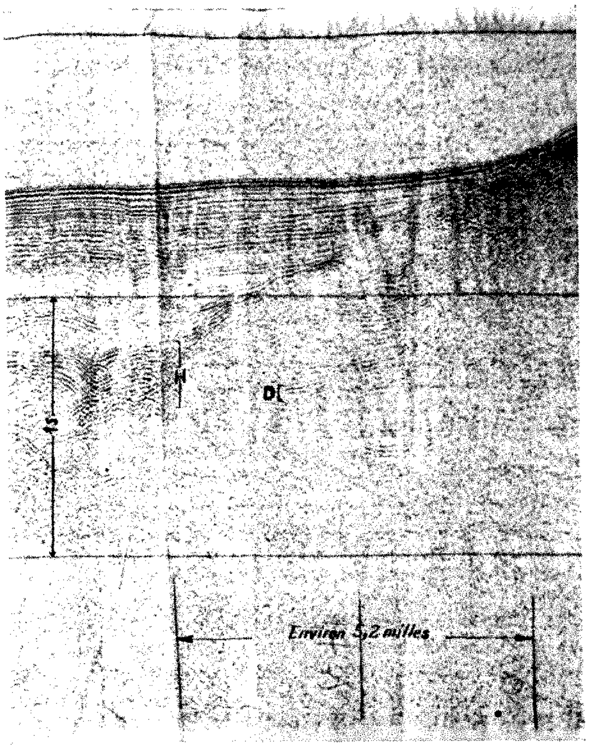

Fig. 3. Sparker record on the continental rise south-east of Levant Island (water depth = 2,400 m). Reflector *H*, and below it, *D*.

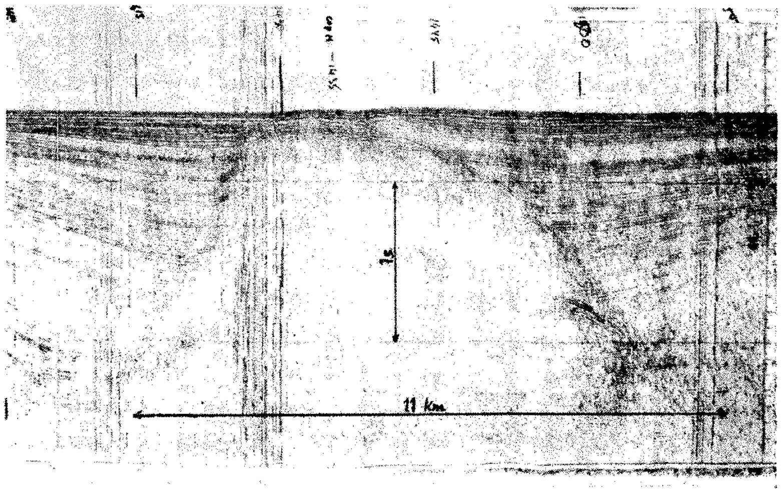

Fig. 4. Typical section of a dome south of Toulon (water depth = 2,400 m).

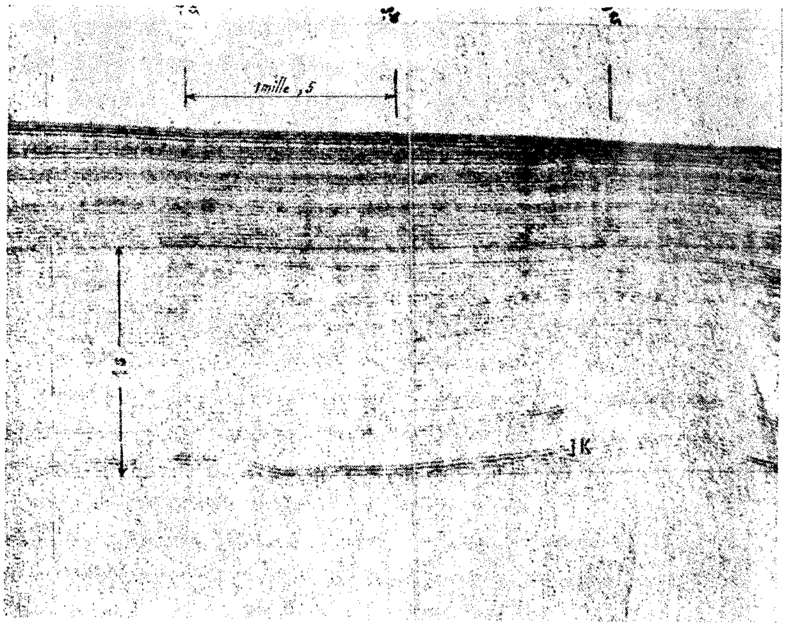

Fig. 5. *K* reflector (west of 06° 00′ E). *K* reflector itself is formed by three phases. The lowest one is corrugated; *K* reflector stays at about 180 ms below a double phase reflexion (water depth = 2,400 m).

Magnetic data therefore indicate Tertiary volcanic deposits such as those found on land, the salt evidently coming from below the *H* horizon (see Fig. 1). The depth of the recorded reflectors, the erosion evidence that can be seen on the *H* level and the probability that there is a deeper level lead to the assumption—following Glangeaud's hypothesis[9]—that this salt basin was formed before the Oligocene or Miocene, as proposed by Stanley and Mutti[1].

Profiling should improve our knowledge of the abyssal structure. Coring from 50 to 100 m under the sea floor will be needed to prove the existence of salt. To determine the date of the *H* and *K* levels, and thus of the entire basin, drilling should be carried out to at least 400 m below the sea floor.

The survey was carried out under contract with the Centre National pour l'Exploitation des Océans and with the help of the Research Committee of the National Geographic Society and the Campagnes Océanographiques Françaises.

Rotation of Sardinia: Palaeomagnetic Evidence from Permian Rocks

PALAEOMAGNETIC data from Middle Tertiary rocks have not decisively shown any rotation of Sardinia[1]. Rocks of Permian age, which seemed most suitable for detecting rotations of the Southern Alps[2,3], Corsica[4] and the Iberian Peninsula[5], were therefore collected in Sardinia in the hope of finding more conclusive evidence.

The samples were collected from several Permian rhyolitic ignimbrites and red sandstones in north-western Sardinia (Fig. 1). The local geology is described elsewhere[6-8].

Laboratory measurements of the rock samples revealed NRM directions with south-easterly declinations and small inclinations. All samples were examined by routine demagnetization techniques with alternating fields up to 3,000 oersteds. With the ignimbrites, alternating fields in general of less than 400 oersteds eliminated small secondary components, resulting in slight adjustments of the directions initially measured. In nearly all ignimbrite samples the total NRM could be practically eliminated at 3,000 oersteds—a typical example is given in Fig. 2*a*. Only in the samples of site 3 did an appreciable part of the NRM (with its characteristic direction) remain even after treatment at 3,000 oersteds (Fig. 2*b*).

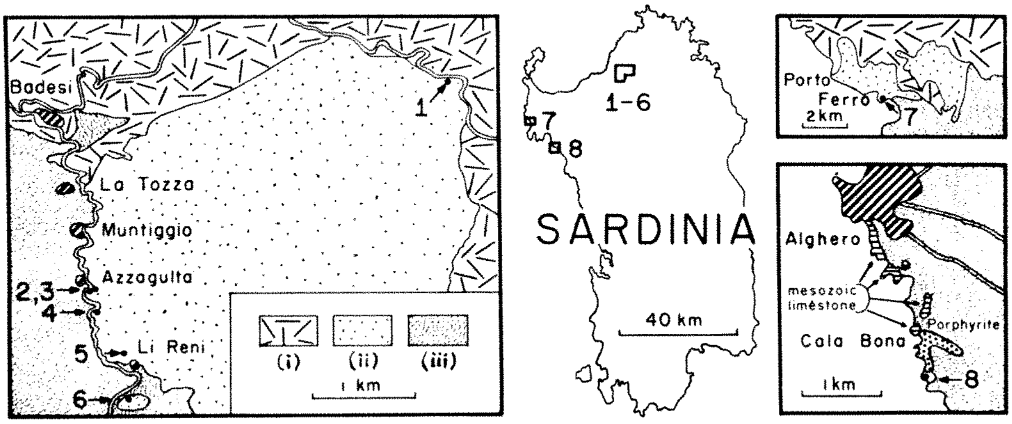

Fig. 1. Simplified geological maps of the sampling regions (after Traversa[7] and Moretti *et al.*[8]) with sampling sites. Key to hatchings: (i) rock basement below Permian volcanics; (ii) Permian volcanics and sediments; (iii) younger volcanics and sediments.

The alternating field demagnetizations of the red sandstones of site 7 showed that their NRM is composed of a very hard characteristic component and a large and fairly hard secondary component. Although the secondary magnetizations of the sandstones could be substantially reduced with the smaller alternating fields, it seemed that a complete elimination could only be achieved with alternating fields as large as 2,000–3,000 oersteds (Fig. 2*c*). The very hard characteristic component was only slightly reduced after treatment in the large alternating fields. The NRM of the red sandstones of site 8 seems to consist only of the very hard characteristic magnetization (Fig. 2*d*). A few thermal demagnetizations of these redbeds yielded results consistent with those obtained from the alternating field demagnetizations. The dispersion of the NRM directions of the red sandstones becomes less after correction for the tectonic tilt.

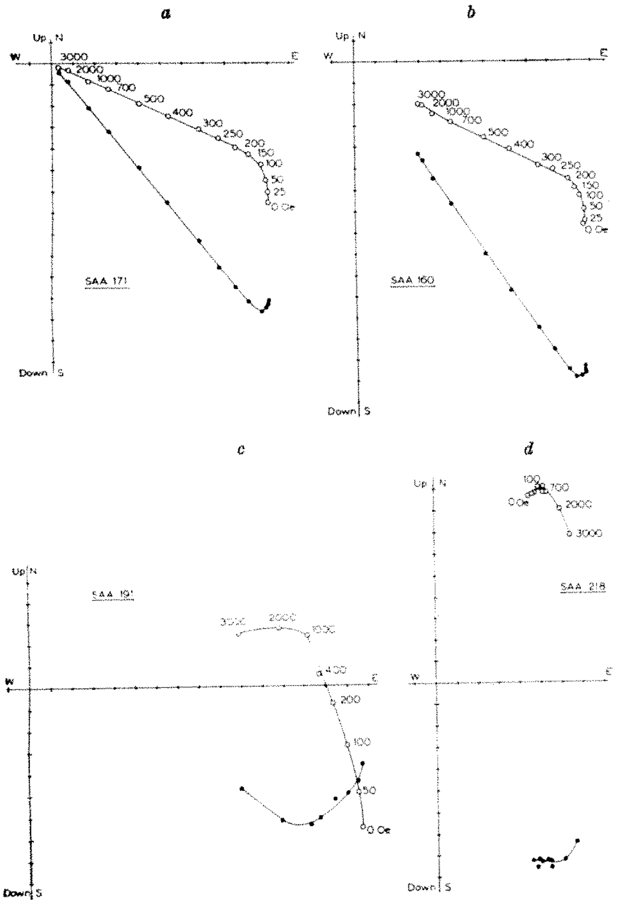

Fig. 2. Four examples of pilot sample demagnetization diagrams, from the rhyolitic ignimbrites (*a* and *b*) and the red sandstones (*c* and *d*). The points represent orthogonal projections of the successive positions of the terminus of the resultant magnetization vector during progressive demagnetization by a.c. magnetic fields. The numbers denote the intensities of these fields in oersteds. Open symbols indicate projections on the east–west vertical plane; full symbols indicate projections on the horizontal plane.

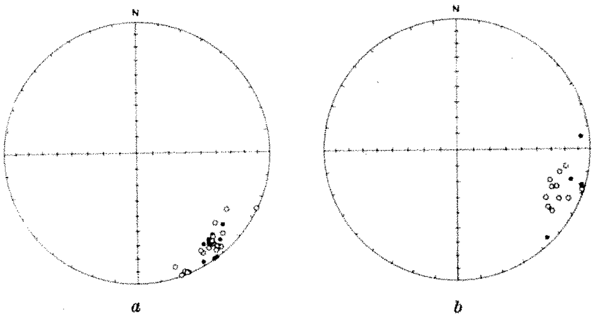

Fig. 3. Directions of magnetizations from the Permian rhyolitic ignimbrites (*a*) and the Permian red sandstones (*b*) after partial demagnetization in a.c. magnetic fields up to 3,000 oersteds and with respect to the bedding planes. Open (full) symbols denote north-seeking poles pointing up (down).

Mean direction of magnetization of the red sandstones ($N = 2$)								—	—	110	−15·5

Table 2. PERMIAN POLE POSITIONS

	Lat.	Long.
Stable Europe, mean	47° S	21° W
Sardinia, ignimbrites	38° S	59° E
Sardinia, redbeds	20° S	91° E
Africa, K3 Galula redbeds	46° S	40° E
Africa, K3 Ketewaka–Songwe redbeds	27° S	89° E

A comparison of the palaeomagnetic results of Sardinia with the only two Permian data available for the African continent reveals a remarkable conformity. The apparent pole position for the ignimbrites of Sardinia is situated halfway between the pole positions of the K3 Galula redbeds and the Ketewaka–Songwe redbeds of Tanganyika, and the apparent pole position for the redbeds of Sardinia is very close to the Ketewaka–Songwe pole position. Because of the restricted number of palaeomagnetic data of Sardinia as well as of Africa, however, a definite conclusion from their conformity seems to be premature.

The mean inclination values of both the Sardinian ignimbrites and the redbeds fit in well with the palaeomagnetic field pattern, extrapolated for the Sardinian region from Permian palaeomagnetic data of the European continent. The mean palaeomagnetic declination values found in the Permian rocks of Sardinia, on the other hand, deviate considerably from the declination value, extrapolated from Permian data of stable Europe. This difference is attributed to a counterclockwise rotation of Sardinia, over approximately 50° in post-Permian times, with respect to stable Europe.

Palaeolatitudes from JOIDES Deep Sea Sediment Cores

IN the framework of plate tectonics the Earth is thought to be composed of a mosaic of rigid plates riding on top of a viscous asthenosphere. The motion of these plates with respect to the Earth's spin axis can be determined using the methods of palaeomagnetism. Measurement of continental rocks[1], oceanic islands[2] and on seamounts[3,4] all yield data which can be used to determine these motions.

Palaeomagnetic measurements of deep sea sediment cores could yield additional information about the past motions of the sea floor. Because of their short length of less than 20 m, however, these cores have been studied principally to determine the frequency and pattern of reversals in the Earth's field during the past 5–10 m.y. With the advent of the JOIDES deep sea drilling programme, cores are now available spanning most of the depositional history of the sea floor.

During Leg II of the JOIDES deep sea drilling programme[5], on station 10 (32° 52′ N, 52° 13′ W), core was recovered spanning a large enough time sequence to enable a reasonable statistical analysis to be made of the palaeomagnetic data. Twenty cores were taken in all and covered two main sequences; the first seven, the Miocene through Upper Eocene, and the last ten, almost the entire Upper Cretaceous (Campanian). Two intermediate cores sampled the Middle Eocene and the Upper Maastrichtian. Opdyke[6] has previously discussed the sequence of polarity reversals recorded in this core. Here we discuss the record of changes in inclination.

The cores on which successful palaeomagnetic measurements were made separate naturally into five groups. Though the relative declination and intensity of the samples vary considerably, the five groups after a.c. demagnetization in a field of 50 oersteds possess absolute values of inclination which are consistent within each group but different between groups. The mean value for for each group, neglecting core 5, for which the intensities were extremely low, decreases with increasing depth in the core (Table 1). The mean value for the three Miocene

* All data included. If one result with an anomalously low inclination is excluded, the mean inclination becomes 54·7°.
† Many intensities are unusually small in this case; mean inclination may be unreliable.
‡ Excluding two values with unusually low intensities ($< 10^{-7}$ e.m.u./g). If these are included, mean inclination becomes 34·2°.

cores is significantly greater than the mean for the Upper Cretaceous (Campanian). When plotted against age, the mean palaeolatitudes decrease uniformly from a latitude close to the 32·9° N latitude of station 10 to a latitude of 19·6° N (Fig. 1).

The Cretaceous palaeomagnetic pole for North America is well located at 69° N, 186° E on the basis of palaeomagnetic results from rocks on the continent[7]. The angular distance between station 10 and this pole is 71°. Station 10 is west of the mid-Atlantic Ridge on a part of the Atlantic sea floor which, according to the concept of plate tectonics, has remained rigidly connected to the continent of North America since the Cretaceous. The predicted inclination for the Cretaceous field at station 10 is 36° whereas the observed value for the Campanian cores is 35·5°. Though this evidence does not prove that the North American plate comprising the north-western Atlantic Ocean and the American continent has remained rigid for the past 80 million years, it is consistent with this assumption.

The internal consistency of the present results is encouraging in view of the many processes which may distort the magnetization of sediments during or after deposition[8]. Especially promising is the possibility of obtaining palaeomagnetic data from parts of the sea floor such as the South Pacific which, unlike the Atlantic, comprise plates that are not rigidly attached to continents. A comparison of palaeolatitudes based on data from unoriented cores collected at well separated sites would test the rigidity of large plates. More important, if it is possible in the future to collect cores that are oriented with respect to azimuth, complete polar paths may be determined for the oceanic plates.

Deep Sea Tide Gauge with Optical Readout of Bourdon Tube Rotations

THE traditional method of measuring the tide by referring sea-level elevations to a stationary structure cannot be applied to the open ocean. Tidal pressure fluctuations on the sea floor, however, are a good indication of the mass variations of the water column. In order to detect changes of water head of 0·5 cm in 5 km depth an instrumental stability and resolution of 10^{-6} is required. Records obtained with vibrating wire transducers, corrected for temperature effects, indicate that this is possible[1-4]. The association of an adequately heat treated Ni Span *C* Bourdon tube with a sensitive optical detector[5] permits deep-sea tide gauges of great simplicity to be made, with ample resolution, negligible temperature dependency and predictable creep characteristics.

The instrument is contained within a heavy-wall aluminium case. The upper end of a freely hanging 42 turn Bourdon helix communicates with the outside. Attached to the lower end of the helix, a small finger supporting a mirror and a magnet dips into a cup of oil that damps its natural oscillations. The rotations generated by the changes of water head (5×10^{-6} radian per centimetre) are sensed by a frictionless, grid-type optical detector and a feedback system.

The functional diagram is shown in Fig. 1. At intervals controlled by a clock, a miniature lamp illuminates through a condensing lens the lower half of a ruling located in the focal plane of an objective in front of the mirror. The light focused on the mirror is reflected back through the objective to form an image of the lower half ruling on the upper half. As the mirror rotates, the ruling image moves with respect to the real ruling, modulating the transmitted light. Solar cells in a balanced configuration intercept it, thus converting the rotations into electrical signals.

Because the periodicity of the ruling is very small, the passage from maximum to minimum transmission requires only minute rotations, and so minute pressure changes. Because diffraction lessens the sharpness of the image, the required linearization is achieved as follows. The amplified signal is applied to a coil surrounding the magnet and the resulting magnetic field produces a torque that twists the Bourdon tube. Rotation of the mirror in turn modifies the signal until equilibrium is reached. The gain of the amplifier is large, and so the error signal is negligible and the meter that measures the nulling current, therefore, also reads the pressure changes.

Because of the periodicity of the rulings, there is a multiplicity of nulls. As the light is interrupted between readings, the system balances with respect to the closest one. The coil current therefore varies between limits $\pm I_{\max}$ and resets to $-I_{\max}+\Delta I$, instead of increasing to $I_{\max}+\Delta I$. So with proper adjustment of the sensitivity the recorded trace shifts to the left when about to run off-scale to the right, and vice versa. The size of the discontinuities generated in the record depends only on stable parameters—namely the grid periodicity, the focal length of the objective, and the elastic constant of the Bourdon tube. They constitute precise and permanent calibrations. The number of nulls depends on the excess width of the incident ruling with respect to the other. At present the grid periodicity is 0·0125 cm, the calibration constant 200 cm, and the available number of nulls approximately 100.

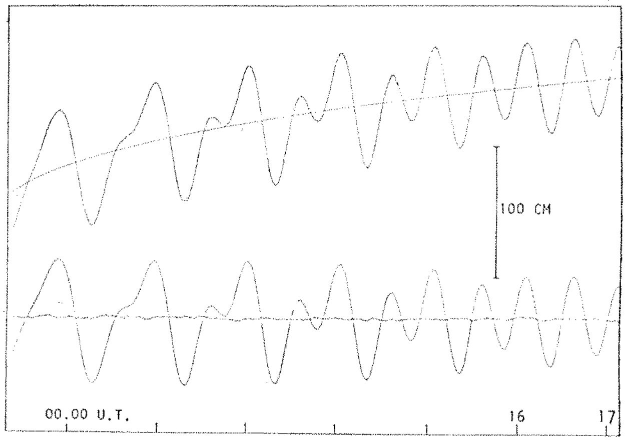

Fig. 2. The upper wavy line, slowly drifting upward, is a plot of the original data. The creep contribution is superimposed on it. The pure tidal and the noise contributions are plotted below.

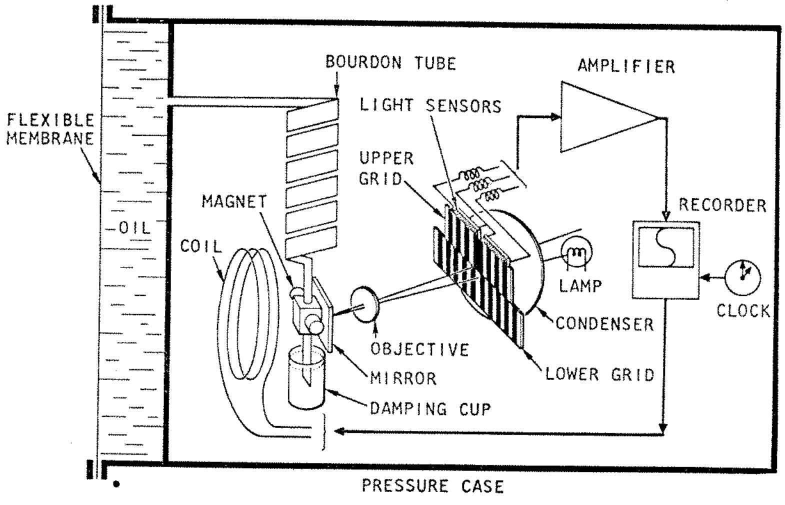

Fig. 1. Schematic diagram of the instrument.

*K*2	30·08214	2·8	1·10 ± 0·12	96 ± 11	5·6	131	4·5	159
*N*2	28·43973	4·5	1·14 ± 0·10	124 ± 10	12·1	119	7·4	178

The inferred constituent amplitudes as well as the observed tidal constants at La Jolla and the prediction by Bogdanov at the point of observation are also indicated. The phase is referred to high equilibrium tide at Greenwich.

The instrument is designed for any oceanic depth. Precentring of the mirror to ± 400 m is required while a final centring using a simple optical sensor and a servomotor is activated after settling on the bottom. The instrument is fastened to a low-profile tripod and anchored in a manner similar to that used for deep-sea mooring of ocean floor magnetometers[6].

Twenty D-size batteries allow 28,800 data points per test, or 1 week of operation at 30 s sampling intervals, 10 weeks at 5 min intervals, and 1 year at 0·5 hour intervals.

A 7 day record obtained during October 1968, in water 4·4 km deep, 1,250 km off the coast of Baja California (position 24° 46·9′ N, 129° 1·1′ W) is shown in Fig. 2. The instrumental drift that was shown to obey Andrade's beta creep law[7,8] is removed easily and on legitimate ground. The tidal constituents can be estimated with an accuracy considerably better than that obtained with coastal records of similar length because of the extreme smoothness of the record and in spite of its short duration. The transfer functions between gravitational driving and tidal response have been estimated together with their uncertainties by a least squares analysis[9]. These estimates as well as the inferred constituent amplitude and phases are listed in Table 1. Comparison with the adjacent coastal amplitudes (Scripps Institution of Oceanography, La Jolla, California) indicates that the offshore attenuation of the semidiurnal tide is considerably larger than that of the diurnal tide. The observed amplitudes are consistently lower than those predicted by Bogdanov's mathematical models[10].

Estimation of Fibril Lengths in Chrysotile Asbestos Fibres

CHRYSOTILE asbestos, the major fibrous serpentine polymorph, occurs naturally as veins in massive serpentine. It has been established[1,2] that chrysotile has a cylindrical crystal habit and occurs as fibrils 200 Å–400 Å in diameter. The orientation of the fibrils in the rock is such that the fibril axis is approximately perpendicular to the vein wall, forming a cross-fibre deposit, and the fibre length is frequently equal to the width of the rock vein; often the fibres grow from both walls and join at a central fissure or break. In commercial usage fibre length is an important characteristic, so various methods of length classification have been developed and applied to commercial raw material. These methods generally apply only to macrofibre bundles, however, each of which contains a large number of parallel fibrils. No data have been published for the fibril lengths of chrysotile, although it is apparent from examination of electron micrographs of dispersed chrysotile fibrils that they exceed several tens of microns in length. This agrees with an aspect ratio of 5,000 derived from strength measurements by Wronski[3]. In addition, Aveston[4] suggests that the somewhat broader fibrillar units of the amphibole asbestos crocidolite have lengths in excess of 1 mm. It is still uncertain, however, whether the lengths of individual chrysotile fibrils correspond to the length of the macro fibres or are shorter, because of defects introduced during growth or by subsequent geological faulting. This uncertainty limits the understanding and full utilization of the properties of chrysotile, in particular its mechanical properties.

With the increasing technological importance of chrysotile, particularly as a reinforcement in high strength materials, where aspect ratio is a critical parameter, it was necessary to undertake a detailed investigation of fibril length using a number of techniques, fuller accounts of which will be published elsewhere.

Samples for fibril length measurement were prepared by gentle stirring of fibre bundles in an aqueous surfactant solution producing dispersed, mainly single fibrils. Great care was taken to minimize fibre damage.

It is impossible to measure directly the lengths of long fibrils from electron micrographs such as Fig. 1, because their length greatly exceeds the field of view of the microscope at the magnification necessary to resolve individual fibrils. A statistical method has therefore been developed which relates the fibril length to the ratio of the number of fibrils to fibril ends visible in a field of view of known dimensions.

A feature of this method is that only individual fibrils are counted and therefore the length values relate to fibril units and not to macro fibres. The method has been verified using simple model systems of randomly distributed rods.

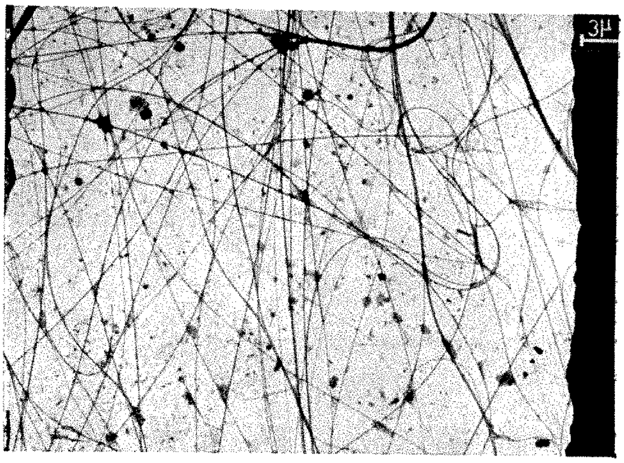

Fig. 1. Typical electron micrograph of long chrysotile fibrils.

Typical values of fibril lengths, estimated for some chrysotile samples, are shown in Table 1.

Table 1. COMPARISON OF ESTIMATED VALUES OF FIBRIL LENGTHS

Chrysotile sample	Mean estimated lengths (mm) Direct measurement from electron micrographs	Statistical measurement from electron micrographs	Drag reduction method	Viscosity method
Mechanically shortened fibril suspension for drag calibration	$1\cdot6\times10^{-2}$	—	Calibration sample	$1\cdot4\times10^{-2}$
Canadian (Cassiar)	$>1\times10^{-2}$	1·8	1·7	5–11
Canadian (Bells)	$>1\times10^{-1}$	1·4	1·7	2–2·5
South African (Kaapsche Hoop)	$>1\times10^{-1}$	4·0	3·9	—

Confirmation of the length values estimated by electron microscopy has been provided by examination of the rheological properties of aqueous suspensions of chrysotile. It has been suggested[5] that a relationship exists between the aspect ratio of fibres added to a turbulent flow system and the resultant reduction in frictional drag or increased rate of flow. An apparatus has been constructed and calibrated to measure this effect, from which values of aspect ratios of chrysotile fibrils have been estimated (Table 1) and lengths calculated, on the assumption of an average diameter of 400 Å.

In addition, attempts have been made to estimate the lengths of fibrils by viscosity measurements on aqueous suspensions. Lengths calculated from Burgers equations[6] have been found to disagree with directly observable lengths of mechanically shortened chrysotile fibrils in suspension. It has been shown[7], however, that curved fibrils deviate significantly from the Burgers model and can produce anomalously high values of aspect ratio, and it is therefore suggested that the curved, flexible nature of chrysotile fibrils (see Fig. 1) is responsible for this discrepancy.

From the work outlined here the following conclusions can be drawn. Carefully dispersed samples of chrysotile fibres, several centimetres in length, have been shown to be composed of fibrils at least several millimetres long—that is, within one order of magnitude of the macro-fibre length. This corresponds to an aspect ratio of approximately 10^5, an extremely high value for an inorganic single crystal whisker. There is, however, some evidence that even the gentle process of separating fibrils from their parent bundles could have resulted in some fibril shortening. The possibility therefore remains that the fibrils are of the order of centimetres long, and extend the whole length of the parent fibre bundles.

We thank H. D. Ellis (AUWE) for advice on the frictional drag techniques and H. G. D. Williams (Turner

Brothers Asbestos) for his part in deriving the statistical analysis.

Melting of Very Small Particles during Evaporation at Constant Temperature

THE dependence of the melting point of small solid particles on their size is implicit in the work of J. J. Thomson[1] on the effect of size on phase equilibria. It has been shown that large depressions of melting point are found when the diameters of the particles are about 20 nm. Takagi[2] and Blackman and Curzon[3] used electron diffraction techniques to study the melting of such small particles. The particle sizes in the latter case were determined by electron microscopy. Further systematic studies have been carried out by Wronski[4] with tin, and by C. J. Coombes (private communication) on lead (see also refs. 5–7).

A new method for observing the melting point of individual gold particles is described in this communication. Particles of solid gold were maintained at a constant temperature, somewhat below the bulk melting point, in a JEM 6A electron microscope. At this temperature, the rate of change in the size of the particles, caused by their evaporation, can be conveniently measured (see ref. 8 for similar measurements on silver). Instead of the monotonic evaporation curves of the kind found for silver particles, the results showed a distinct change in the rate of evaporation of particles (see Fig. 1) at a size which was dependent on temperature.

The change in evaporation rate is caused by melting of the gold particles. This change occurs because the solid gold particles have an evaporation coefficient less than unity[9], while the molten particles have an evaporation coefficient of unity.

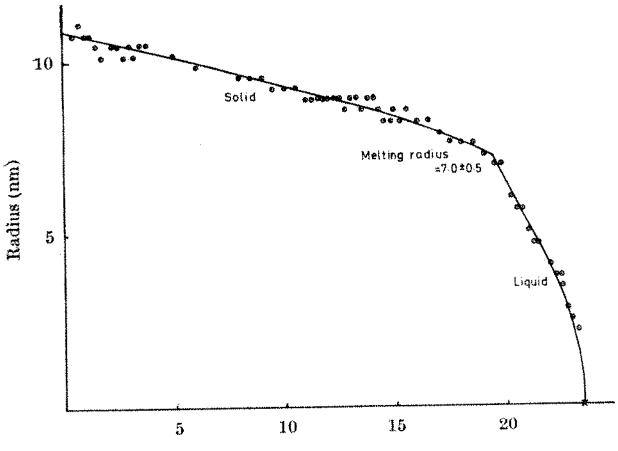

Fig. 1. The evaporation of a gold particle, $T = 1{,}229 \pm 5$ K. X marks the time when the particle became unresolved in the electron microscope image.

A series of experiments were carried out at different temperatures (T) over the range 1,150 to 1,330 K. These temperatures were determined from the rate of evaporation of the liquid particles; the radius of a particle at the melting point was taken at the sudden change in the rate of the evaporation curves.

It is to be expected that the reduced temperature, T/T_m (T_m being the bulk melting temperature), plotted as a function of the radius would give a universal curve for materials with similar properties and similar crystal structure. The results of Coombes (private communication), for lead, fit within experimental error the curve drawn for gold; surprisingly, the data for tin found by Wronski[4] also fit the same curve.

A detailed account of this work will be published later. One of us (J. R. S.) thanks the Science Research Council for a maintenance grant.

Increasing Permeability of Polymer Membranes by Irradiation in the Fully Swollen State

THE permeability of polyolefin film may be made selective towards a particular solvent by annealing the film below its dissolution temperature in that solvent. For example[1,2], a selectivity towards *p*-xylene in a mixture of *o*, *m* and *p*-xylenes has been conferred on a polyolefin membrane in this way. Michaels and co-workers[3] have extended this to other solvents and were able to increase permeability as much as fifteen-fold relative to untreated membranes, but with reduced selectivity toward the permeants. These enhanced permeabilities were, however, not permanent. We demonstrate here[4] that when solvent annealing of a polyethylene film is followed by cobalt-60 γ-irradiation —while the film is still in contact with the annealing solvent—permeabilities are greatly increased. The enhancement produced by a combination of irradiation and annealing, however, is not only greater than that caused by annealing alone, but is far more permanent.

Polyethylene films were pretreated by soaking for about 48 h in solvent and then irradiated for different times in the same solvent. After irradiation, the films were dried before being placed in the permeation medium, except when this medium was identical with the irradiation solvent.

All permeation measurements and annealing of films were carried out at 30° C. During irradiation, the temperature of the medium fluctuated between 33° C and 38° C; the higher temperatures resulted from γ-ray heating but were not large enough to account for the observed increases in permeability. The experimental procedure and apparatus have been described[5]. The technique eliminated non-uniformity along the transport path within the films and yielded transport rates for films fully and uniformly equilibrated with the liquid permeation medium.

Low-density polyethylene films were exposed to γ-radiation while fully swollen. The results are identified by the code $X_1X_2(t)X_3$. Here X_1 identifies the permeant or tracer molecule, X_2, the irradiation medium, and X_3 the permeation medium. The number in parentheses (t) is the number of hours the film was irradiated while it was in solvent X_2. C = Cyclohexane, T = toluene, B = benzene, A = air; 0 in position X_2 means that the film received no irradiation treatment.

The results are given in Table 1 and also plotted in Fig. 1 where the effects of irradiation in solvent on increasing permeability are evident. It is also possible to estimate the increase in selectivity with respect to benzene and toluene, if the film is irradiated in toluene. It is best to write the results as follows:

System	$P\times10^7$ (cm²/s)	Selectivity $= P_B/P_T$
BOT	5·45	1·31
TOT	4·14	
BT(3)T	8·08	1·63
TT(3)T	4·96	

Clearly, for the separation of small amounts of benzene from toluene, pre-irradiation of a toluene-annealed film for 3 h increases the selectivity by about 24 per cent. Pre-irradiation of the film in benzene and longer irradiation periods might cause even larger increases in selectivity.

Films prepared as we describe exhibit no substantial loss of enhanced permeability after treatment by annealing and irradiation and subsequent removal from contact with the solvent; the permeability has been rechecked for up to 500 h after such treatment and no loss of the enhancement was observed. The effect therefore lasts at least five times longer than that observed by Michaels[1,2].

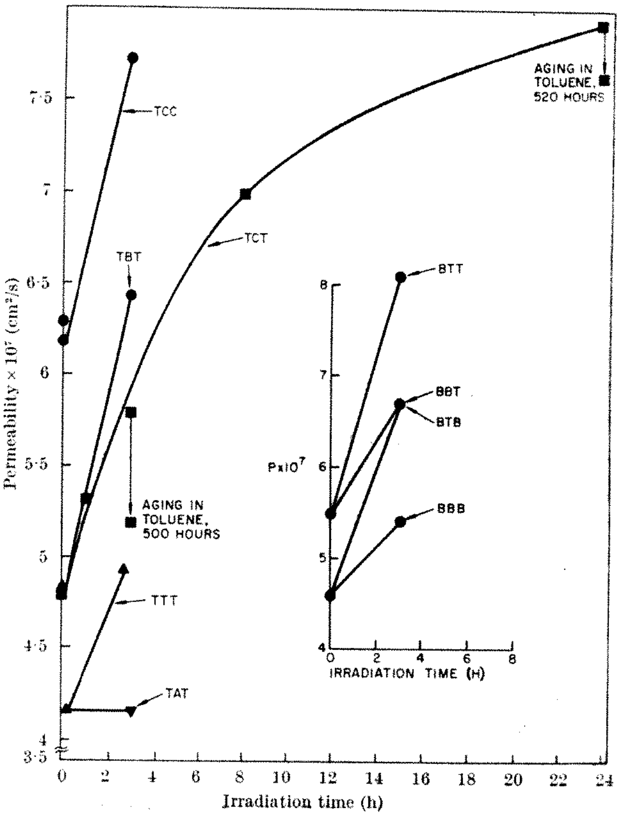

Fig. 1. The permeability data of Table 1 plotted to show the effect of irradiation time on membrane permeability. Dose rate = $0·85\times10^6$ rad/h; permeation temperature, 30° C.

In the light of Michaels's recent report[3], far greater enhancement of permeability might be expected if simultaneous annealing and irradiation are carried out at higher temperatures (but below the temperature of complete dissolution). Our experiments indicate that permeabilities were in some cases about doubled by annealing and irradiation at room temperature. Michaels *et al.*[3] reported permeability enhancement (of the non-permanent kind) up to fourteen times by solvent annealing at higher temperatures. Thus even greater permeability enhancement (which should also be permanent) would be expected by combined solvent annealing and irradiation of polymeric membranes at elevated temperatures.

To explain the process of solvent annealing, a polyolefin film may be viewed as a system of spherulitic polymeric crystallites embedded within an amorphous polymeric matrix. Diffusive transport within this system takes place predominantly within the amorphous part. When this system is annealed in a good solvent at an elevated temperature, the larger spherulitic crystallites may be expected to grow at the expense of the smaller ones, which simultaneously disappear. Thus the annealing process leads to larger crystals and a coarser network of spherulitic polymeric crystals within the amorphous polymeric matrix. The structure becomes more open and diffusive transport through this matrix of coarser, relatively impermeable spherulites is thereby enhanced.

The effect of γ-irradiation on the solvent-annealed polymer is presumably to produce free radicals at sites both within crystallites and within the amorphous matrix. This results in cross-linking which binds together the polymer chains within the enlarged crystallites into permanent structures that will not redissolve. Cross-linking of this type probably puckers the structure and destroys to some extent the crystalline regularity and perfection (cross-linking polymers by γ-irradiation is known to decrease crystallinity). Nevertheless, the net result would be to leave the former crystallites as dense, tightly bound entities. Moreover, interaction between free radicals produced within the amorphous phase and those produced at the surfaces of crystallites would bind polymer segments from the amorphous phase to the crystallites; this would produce additional holes within the permeable amorphous phase and thereby further enhance the permeability of the overall system.

Irradiation of swollen membranes seems to enhance their capacity to discriminate between molecules, as well as their permeability, to a degree associated with fully swollen polymers. The potential application of such membranes is evident in areas such as dialysis, ion-exchange, reverse osmosis and other separation processes.

Non-dissociative Reaction of Oxygen with Metals

DURING our matrix isolation studies of the infrared spectra and structures of molecular species in metal oxide vapours[1-4], we have made some observations that are of interest in a completely different context—the primary reaction step in metallic corrosion.

Gaseous metal oxides may be formed readily as high temperature vapour species, either by heating the solid oxide or by passing oxygen gas at low pressures over the heated metal. Using both these methods we have obtained infrared spectra assignable to molecules M_xO_2 (M = Ge, Sn, Ga, In, Tl). Mass spectrometric evidence[5] suggests that M_xO_2 molecules may be important components of the vapours in numerous systems. Evidence that our species contain two equivalent oxygen atoms is based, in part, on the effect of ^{18}O-enrichment of the parent oxides, which then produce three isotopic molecules on vaporization: $M_x{}^{16}O^{16}O$, $M_x{}^{16}O^{18}O$, $M_x{}^{18}O^{18}O$.

When mixtures of $^{16}O_2/^{18}O_2$ gas, containing negligible amounts of the molecule $^{16}O^{18}O$, are passed over heated germanium, tin, gallium or indium, the spectra produced are identical with those obtained from the ^{18}O-enriched solid oxides, and prominent infrared bands are observed for the three isotopic species. Isotope scrambling therefore takes place in the formation of the oxide molecule. When the same gaseous mixture is passed over heated thallium, however, virtually no $Tl_x{}^{16}O^{18}O$ is produced, although $Tl_x{}^{16}O^{16}O$ and $Tl_x{}^{18}O^{18}O$ are readily identified (Fig. 1*b*). When the experiment is repeated with partially equilibrated oxygen gas, containing significant amounts of $^{16}O^{18}O$, the corresponding mixed oxide is observed (Fig. 1*c*). These spectra may be contrasted with that obtained from vaporization of solid thallium oxide, where complete randomization occurs (Fig. 1*a*).

We are therefore led to the inescapable conclusion that, in the formation of the oxide molecule Tl_xO_2 by direct oxidation of the metal, both the oxygen atoms must be derived from the same molecule of oxygen. Chemisorption of oxygen on metals is almost invariably dissociative, so that oxygen isotopes are randomized in the formation of volatile polymeric oxide species. On thallium, the initial chemisorption step seems to be non-dissociative.

Dissociative adsorption of any diatomic reactant (O_2, S_2, and so on) implies a sufficiently high energy of formation of the initial adsorption complex. Ehrlich[6] has suggested that, if the adsorption energy is great enough, one atom may be trapped at the site of primary adsorption while part of the adsorption energy is transferred, as translational energy, to the second atom. This then migrates several unit spacings across the surface before it is bound. Isotope scrambling is a necessary consequence of such a process. There is too little information about the adsorption energy of oxygen on metals to warrant any wide comparison between the elements, but it may be surmised that there must be a critical value, below which the act of chemisorption is non-dissociative. In the absence of such data, the enthalpy of formation of the oxides might be taken as a crude measure of the metal–oxygen interaction energy within any one group. For group IIIB, the ΔH_f° values (kilocalories/g atom oxygen) are

$$Ga_2O,\ -82;\ 1/3\ In_2O_3,\ -74;\ Tl_2O,\ -42;$$
$$1/3\ Ga_2O_3,\ -86$$

On this basis it might be predicted from the thermochemical data that few other metals would show the same behaviour as thallium. It may be relevant, however, that Michell and Smith[7] have shown that the oxidation of cadmium in air forms CdO_2, not CdO. Here, too, the chemisorption step involves electron transfer to molecular oxygen, without dissociation. In most cases this may be a very transient precursor stage; in a few cases the reaction products reveal it.

Saturation of a Molecular Absorption Line at 890 GHz

It has been shown[1,2] that the molecule 1 : 1 difluoroethylene CF_2CH_2 has an absorption line close to the main 890 GHz emission line of the HCN laser. The results suggest that the line is about 0·5 MHz from the laser line centre and has an absorption coefficient of $\alpha = 0{\cdot}0008 \pm 0{\cdot}0003$ nepers cm^{-1} at 0·1 torr. Experiments carried out in the laser cavity[1] provided some evidence for saturation of this line. We describe here more explicit observations of saturation both intra and extra cavity.

Two HCN lasers were used in these experiments. A hemispherical configuration, 4 m long with an axial mode diameter of 2·5 cm at the plane mirror and 10 cm diameter at the curved mirror, was used for the intra-cavity measurements. The 1 m absorption cell was placed at the plane mirror to maximize the laser power density in the absorbing difluoroethylene. The laser output was coupled out of the cavity by a beam splitter and detected either by a Golay cell or by a silicon crystal–tungsten whisker diode. The cavity modes were swept by a linear mirror drive or by an oscillating loudspeaker coil on which the plane mirror was mounted. The output power of the laser was of the order of 10–20 mW and the power inside the cavity was approximately 400 mW with no absorbing gas.

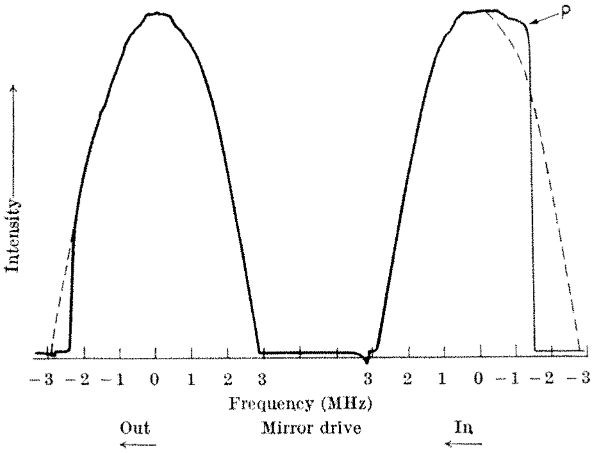

Fig. 1. Laser interferogram with CF_2CH_2 in the cavity. 890 GHz fringes.

With 0·05–0·100 torr of CF_2CH_2 in the cell, Q-switching effects caused by bleaching of the absorber were observed. Fig. 1 shows a typical cavity resonance curve using the linear motor mirror drive. The dotted lines are the symmetrical curves obtained with no gas in the cell. It will be noted that the form of the resonance depends on the direction of the mirror drive: switching on and off occurs at different levels of laser output as would be expected for a saturation phenomenon. Fig. 1 also shows a small Q-switch gain over the CW power level at P. This was the maximum gain observed and there was no evidence of repetitive Q-switching when the plane mirror was oscillating over the resonance at approximately 1 kHz frequency. The switching time was found to be of the order of 100 μs. The absence of any large Q-switch gain confirms the observations of Jones *et al.*[3], who used a rotating mirror in a Q-switched CW HCN laser. The apparent gain could not be interpreted as an inverse Lamb dip effect caused by saturation hole burning in difluoroethylene gas[4,5]. At 0·05 torr the collision broadened line width is approximately 1·0 MHz[1], which is considerably less than the laser tuning width (8 MHz) and hence distinctive enough to show up independently of the mirror drive direction. In any case, in this configuration of laser and absorption cell the power would homogeneously broaden the dip at the low pressures necessary for $\Delta\nu_{\text{collision}}$ to be less than $\Delta\nu_{\text{Doppler}}$ (see below).

The external cavity absorption experiments were carried out in a 6 m long brass cell 2 cm in diameter. The HCN laser used was near confocal, 6·5 m long, 10 cm in diameter and had a power output of about 50 mW coupled out of the cavity by means of a 2·5 cm hole in one of the mirrors. The absorption coefficient as a function of laser power for 0·04 torr gas pressure is shown in Fig. 2. The broadening caused by saturation is immediately obvious. Calculations from these data are complicated by the nature of the line. Thus the Doppler width is approximately 1·4 MHz and the collision self-broadening width for 0·04 torr is 0·8 MHz[1]. A convolution of the two shapes for the line[6] leads to a width of 2·0 MHz which is observed, although the uncertainty in pressure measurement is ± 20 per cent.

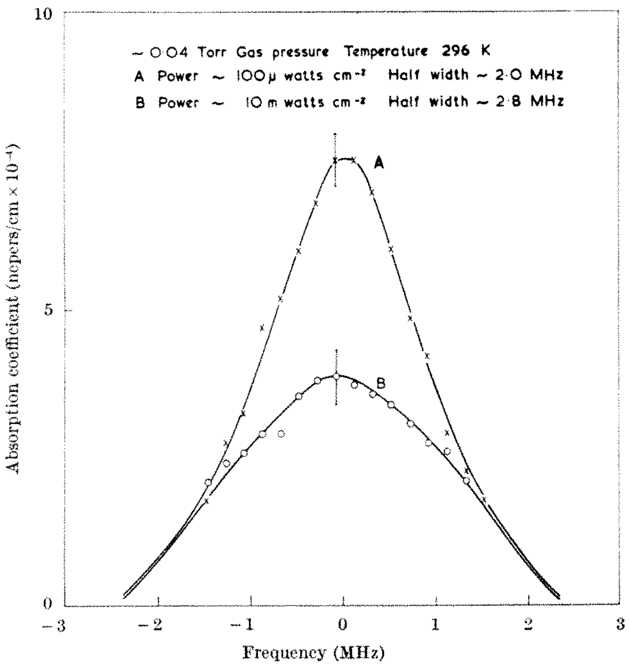

Fig. 2. Saturation in CF_2CH_2 at 890 GHz, 6 m external cell.

A general form for the absorption coefficient for saturation of a homogeneously broadened line is given by Townes and Schawlow[7] as follows:

$$\alpha = \alpha_0 \left[1 + \frac{32\pi|\mu_{01}|^2 P}{3ch^2\Delta\nu^2} \right]^{-1} \tag{1}$$

where P is the radiation power, $|\mu_{01}|^2$ the dipole matrix element for the transition and $\Delta\nu$ is the full line width. This is expected to be modified for inhomogeneous (Doppler) broadening[9], but it will serve for the purpose of discussion.

Approximate calculations indicate that the rotational transition in CF_2CH_2 is in the region (J, Ka, Kc) 49, 38, 11→48, 38, 10 (unpublished work of G. Duxbury and D. Finnigan) which is approximately 750 cm^{-1} above the ground level. Absolute assignment is complicated by the lack of centrifugal distortion information. Using the measured dipole moment[7,8] of 1·385 Debye leads to a value of $|\mu_{01}|^2$ of 0·5 to 1 Debye[2]. Substituting in the above equation gives $\alpha = \alpha_0/2$ for P equal to about 10 mW cm^{-2}. This value has only qualitative significance because the power as measured by a Golay cell may be uncertain.

An experiment has been carried out in which the output of the laser was split into two beams which were directed through the absorption cell in opposite directions. Preliminary results indicate that a saturation dip is observable in difluoroethylene in these conditions. This may be of use in the frequency stabilization of the HCN laser.

We thank Dr N. W. B. Stone for his advice and encouragement and Mr J. Dromey for technical assistance.

BIOLOGICAL SCIENCES

Blocking of the Lymphocyte Antigen Receptor Site with Anti-immunoglobulin Sera *in vitro*

ALTHOUGH the events occurring during the induction of an antibody response are not clearly understood, it is evident that antigen must react with some type of receptor which is either free in serum or present at a cell surface. Various experiments[1-3] in which labelled antigen is allowed to react *in vitro* with lymphocytes suggest that a very small proportion of all lymphocytes does in fact have the ability to recognize and bind a given antigen. The specificity of this binding reaction between antigen and lymphocyte was demonstrated in both adoptive transfer experiments[4] and *in vivo*[3]. Electron microscopic studies indicate that the reactive lymphocytes possess localized receptor sites for antigen on their surface[5]. Preliminary studies[2] showed that pretreatment of these cells with a polyvalent anti-immunoglobulin serum inhibited antigen binding and suggested that the antigen receptor site involves some type of immunoglobulin molecule. We now report in more detail on the nature of the receptor sites on lymphocytes and suggest that interaction of antigen with these sites is crucial in the induction of the antibody response.

Normal CBA mouse spleen or peritoneal cell suspensions were preincubated with a 20–50 per cent final concentration of different, specific anti-mouse immunoglobulin sera (or control normal sera) for 2 h in an ice bath, and the cells washed by centrifugation through a foetal calf serum gradient. The cells were then allowed to react with ^{125}I or ^{131}I-labelled antigens at 0° C for a further 30 min, centrifuged through serum gradients and finally smeared on glass slides for the preparation of autoradiographs. The procedures for labelling of antigens, preparation of cell suspensions, autoradiography and counting of labelled cells have been described[2]. Antigens used[2] were flagellin and polymerized flagellin from different *Salmonella* strains and haemocyanin (*Jasus lalandii*).

In a second type of experiment, cell suspensions pretreated as above with anti-globulin sera, were injected into lethally (850 rad) irradiated syngeneic mice (groups of eight per cell suspension) together with an immunogenic dose of unlabelled antigen. The recipient mice were then bled either 8 or 14 days later and serum samples titrated for antibody activity.

Anti-mouse immunoglobulin sera were prepared by repeated immunizations of rabbits with purified mouse myeloma proteins emulsified in Freund's complete adjuvant. The sera were rendered heavy chain specific by appropriate absorptions with either mouse immunoglobulin light chains or myeloma proteins of another immunoglobulin class. The specificity of the absorbed antisera was verified by use of the very sensitive inhibition of precipitation assays of ^{125}I-labelled mouse myeloma proteins as previously described[6].

Table 1. EFFECT OF ANTI-IMMUNOGLOBULIN SERA ON THE ABILITY OF NORMAL MOUSE SPLEEN CELLS TO BIND ^{131}I-LABELLED ANTIGENS

Rabbit antiserum pretreatment (0° C, 2 h)	Percentage of control antigen uptake*	Mean per cent control†
Normal serum	69, 74, 110, 138	98
Anti-human serum albumin	101, 125	113
Polyvalent anti-LH chain	<10, 11, 12, 23	<14
Anti-L-chain	6, 10, 11, 14, 33, 38, 90	29
Anti-L-chain preabsorbed with mouse L chains	100, 170	135
Anti-α-heavy chain	71, 90, 105	89
Anti-γ_1-heavy chain	90, 94, 100	95
Anti-γ_2-heavy chain	72, 99, 150	107
Anti-μ-heavy chain	7, 33, 51	30

* Each value represents an individual experiment performed with either *Salmonella* flagellin or haemocyanin as antigen. Each value is the percentage of antigen uptake for the serum treated cells as compared with the control cells with no serum. Antigen uptake is scored as the number of labelled lymphocytes per 10^6 cells.

† Mean of the individual values.

The results with all antisera are presented in Table 1, in which the percentage of control antigen uptake is shown. All controls (no serum pretreatment) showed the usual level of labelled cells. Each value represents an individual experiment, and the mean values clearly indicate that significant inhibition of antigen uptake by cells was achieved only with antisera containing antibodies either to immunoglobulin light chains or to μ (macroglobulin) heavy chains.

To determine whether these same cells with IgM surface receptors were indeed involved in the primary antibody response, antiserum treated cell suspensions were injected together with various antigens into irradiated mice. The results (Table 2) indicate that marked suppression of antibody formation has been achieved by pretreatment of cells with either anti-light chain serum or an antiserum containing predominantly anti-μ-chain antibodies. This particular anti-μ-chain serum was unabsorbed and contained traces of anti-light-chain activity. In view of the concentration of the anti-light-chain serum required to achieve inhibition, it is unlikely that the trace of anti-light chain antibody present in the anti-μ-chain serum was responsible for its inhibitory activity. Specific anti-γ-chain sera did not inhibit this response.

A preliminary examination has also been made of the nature of antigen binding receptors on lymphocyte-like cells from other sources. Peritoneal cell suspensions (from the normal peritoneum and not oil induced exudates of adult mice) contain a very high proportion of cells which bind antigen. With both antigens used inhibition of binding occurred after treatment of cells with a polyvalent anti-immunoglobulin serum (24 per cent of control uptake) although this reduction was not as marked as with adult spleen cells. A similar degree of inhibition (29 per cent) was observed with newborn mouse spleen cells and a greater inhibition (7 per cent) with spleen

Table 2. EFFECT OF ANTI-IMMUNOGLOBULIN PRETREATMENT OF NORMAL MOUSE SPLEEN CELLS ON THEIR ABILITY ADOPTIVELY TO TRANSFER PRIMARY ANTIBODY PRODUCTION TO IRRADIATED RECIPIENTS

Antigen	Serum preatment (0° C, 3 h)	Antibody titre in irradiated recipients (log$_2$)*		Significance (P value) compared with normal serum or no serum
		Day 7–9	Day 14	
Polymerized flagellin SW 1338	No serum	2·5	—	
	Preimmune normal serum	2·5	—	
	Anti-μ (trace L)	1·2	—	< 5, > 1%
Polymerized flagellin SL 871	Normal serum	7·3	—	
	Preimmune normal serum	8·2	—	
	Anti-L-chain	3·7	—	1%
Brucella abortus	Preimmune (anti-L) normal	—	8·5	
	Anti-L-chain	—	4·1	1%
	Anti-μ-chain (trace L)	—	5·0	1%
Sheep erythrocytes	Preimmune (anti-L) normal	—	3·5	
	Anti-L-chain	—	1·0	1%
	Anti-μ-chain (trace L)	—	< 1·0	1%

In each experiment the preimmune normal serum is the preimmunization bleed of the anti-μ or anti-L rabbit.

* Bacterial immobilization was used for flagellin, agglutination assay for *Brucella* and sheep erythrocytes.

cells from 3 day old mice. Further studies are in progress to determine whether the incomplete inhibition observed with newborn mouse spleen and adult peritoneal cells is attributable to a phagocytic type of cell not involved in specific antigen recognition.

Our results, combined with related studies[2,3,5], strongly suggest that lymphocytes from unimmunized mice have at their surface IgM macroglobulins which specifically bind antigens. Other studies have indicated that the normal lymphoid cell population contains two discrete populations of cells: thymic derived cells involved primarily in cellular immunity and bursal (or bursal equivalent) derived cells involved in humoral antibody formation[7]. From the result of the *in vivo* cell transfers in these and other studies[3], it is probable that these lymphocyte-like cells are involved in humoral immune responses. Thus differentiation of haemopoietic stem cells towards antibody producing precursor cells would involve the expression of the light and μ-chain immunoglobulin genes, with a resulting localization of the IgM molecules on the cell surface. This is supported by the observation[8] that IgM is the first immunoglobulin synthesized within the bursa of Fabricius itself, which is the first location of immunoglobulin synthesis in chickens.

This suggests that further differentiation toward cells secreting large amounts of antibody is induced by contact of antigen with the surface IgM receptor. Further, if all normal antibody producing precursor cells carry these IgM receptors, indicative of μ-chain gene activity, then the resulting IgG antibody formation which occurs in many responses may reflect an intracellular switch from the μ-chain gene to the γ-chain gene, as has been suggested[9]. Alternatively, different cells may possess IgM, IgG and other immunoglobulin class receptors, but there is a preponderance of cells with IgM receptors.

These results may also be compared with those from a similar approach, involving the use of the same antisera to identify the nature of the antigen recognition site on cells mediating cellular immunity[10]. Cell suspensions pretreated with antisera were assayed for immunological competence in either graft versus host reactions or in the cellular transfer of delayed hypersensitivity. In the latter systems, almost complete suppression of activity was achieved with the anti-light-chain serum, but by contrast with the results now reported, no anti-heavy-chain antibody (including anti-μ-chain antibody) had any inhibitory activity.

Thus the initial contact between antigen and normal unprimed cells involved in either cellular or humoral immunity involves a cell surface bound immunoglobulin molecule as the unit of recognition, and it is intriguing to consider that a different class of immunoglobulin is involved in the two systems. Further studies with ^{125}I-labelled purified anti-immunoglobulin antibodies, now in progress, may demonstrate directly the location of the immunoglobulin receptors on the cell surface.

In vitro Reactivity of Lymphocytes to Particulate and Soluble Antigens

NUMEROUS reports have documented the response of sensitized peritoneal exudate cells to various antigens, including PPD, BCG and ovalbumin[1-8]. By contrast, migration inhibition studies of sensitized peripheral lymphocytes without the addition of macrophages have either been inconsistent or negative[9,10]. Johanovsky, using a splenic explant system, obtained consistent migration inhibition to a number of particulate and soluble antigens; his system did, however, contain a number of different cell types[11]. The previous reports by Bendixen and Søborg that the migration of sensitized human leucocytes could be inhibited by various particulate antigens such as *Brucella* or organ extracts suggested that the sensitized lymphocyte could, in fact, respond to an antigenic stimulus provided the antigen was in a certain form[12-14]. The concept of a particular antigenic configuration being required for the stimulation of the sensitized lymphocyte was further confirmed by our consistent observation of the inhibition of migration of sensitized lymphocytes to transplantation antigens, streptococcal structures, and heterologous erythrocytes (refs. 15, 16 and our unpublished work). In each case the presence of a particulate form of the antigen seemed to be indispensable for inhibition of migration.

To assess further the difference between particulate and soluble antigens with respect to the inhibition of migration of sensitized lymphocytes, tuberculin sensitized human and rat lymphocytes were exposed to various tubercle products. The response to particulate and soluble antigens was assessed by (1) the inhibition of migration of lymphocytes from capillary tubes, and (2) increased DNA synthesis in response to antigenic confrontation. The animals were derived from our own breeding colony and consisted of an inbred strain of Fischer rats, maintained by strict brother to sister mating: they were fully inbred. The rats were sensitized to tuberculin by an intraperitoneal and bilateral subcutaneous injection of a total of 1 ml. of Freund's complete adjuvant (FCA) (Difco Laboratories). Ten days after the first injection a second injection of an equal volume was given. The animals were used in these experiments 8 to 12 days after the second sensitization.

In the experiments with human lymphocytes, normal healthy individuals, as well as patients from the local hospital with diseases other than tuberculosis, were used. All of these patients gave a history of having previously been sensitized to tuberculin by vaccination with BCG. The time since vaccination ranged from 5 to 50 yr. Previous exposure to the tubercle bacillus was ascertained by intradermal skin testing with first and intermediate strengths PPD (Difco Laboratories). The reactions were graded as positive if an induration of more than 5 mm was observed 48 h after intracutaneous injection of the material.

The separation and preparation of lymphocytes from rats and humans for the inhibition of migration studies and the ^{14}C-thymidine incorporation experiments were as previously described[15–17]. In general, the lymphocyte preparations contained less than 10 per cent granulocyte contamination in these studies. For the migration studies, the percentage of migration was calculated as follows:

$$\frac{\text{Area of migration with antigen}}{\text{Area of migration without antigen}} \times 100$$

DNA synthesis induced by the different antigens was determined by adding 0·1 μCi ^{14}C-thymidine (Radiochemical Centre, Amersham) for 24 h to each tube. Preliminary experiments indicated that the optimal time for addition of the isotope was 96 h after the initiation of the experiments. When phytohaemagglutinin (PHA) was used, the ^{14}C-thymidine was added 48 h after initiation of culture. The tubercle bacilli used in these experiments were cultured by the State Bacteriological Institute, Stockholm. These bacilli were harvested and killed by heating. One to two million organisms per ml. were used for most experiments. Purified protein derivative (PPD) was supplied by the State Serum Institute, Copenhagen, without any preservative and contained 1 mg per ml. of PPD. This solution was diluted to the appropriate concentration with the previously described medium.

Table 1 illustrates the results obtained with sensitized human and rat lymphocytes to the tubercle bacillus and PPD. At concentrations of 1×10^6–2×10^6 organisms per ml., tubercle bacilli significantly inhibited the migration of sensitized lymphocytes, whereas there was no response to 20 or 50 μg of PPD per ml. Sensitized rat spleen cells responded similarly to the tubercle bacillus while again no response was observed with the soluble PPD. Control non-sensitized animals did not respond significantly to either form of the antigen. Similarly, skin test negative human subjects failed to show a significant inhibition.

Table 2 illustrates the response of tuberculin sensitized human lymphocytes to the tubercle bacillus in the capillary migration system and to PPD as it affects the level of DNA synthesis after five days of culture with the antigen. Clearly the lymphocytes of tuberculin sensitized human subjects do respond to soluble PPD antigen as measured by the incorporation of ^{14}C-thymidine, but the correlation between the two tests—namely, inhibition of lymphocyte migration and the level of DNA synthesis—was variable. Because the latter method measures the response of both antigen-sensitive cells and antibody-producing cells after prolonged incubation, variations between the two tests might be expected.

The use of a pure lymphocyte population in the capillary migration system has been the subject of considerable dispute. While both positive (ref. 12 and our unpublished work) and negative[10] results have been reported, successful inhibition of lymphocyte migration may well depend on a particular antigen configuration. Here a significant response was observed with sensitized lymphocytes in either human or rat subjects if the antigen was in a particulate form. By contrast, negligible inhibition of migration was observed when soluble PPD was present in the medium. A significant response was observed, however, when sensitized lymphocytes were exposed to the soluble antigen during a five day period of culture. We suggest that in order for lymphocyte migration inhibition to occur, the antigen must be in a particulate form and perhaps of a certain configuration. The basis of this reaction and the reason why a particular form of antigen seems to be essential for inhibition of lymphocyte migration are being studied.

Suppression and Enhancement of Antibody Formation by Alteration of Ca^{2+} Levels

IT is becoming clear that membrane events are important in antibody formation—in the recognition and handling of immunogens, in the activation and multiplication of antibody-forming cells, and in the interaction of the several cell types involved[1]. Various agents (for example, chlorpromazine, epinephrine, antilymphocyte sera and phytohaemagglutinin) known to alter membrane permeability can change the magnitude and, in some cases, the specificity of the antibody response, but most of the reported effects had been transient and weak[2-6]. Because calcium ions are known to influence many membrane-associated events[7-23], we tested the influence of altered levels of Ca^{2+} on antibody formation *in vivo*, and have observed striking changes which, depending on the timing of the alteration, involved either enhancement or suppression of responses to sheep red blood cells (SRBC) in mice.

Female CFW mice (6–8 weeks old) were immunized intravenously with 10^8 SRBC and the number of antibody-forming spleen cells (AFC) was determined 48 or 72 h later[24]. Treatments designed to change levels of Ca^{2+} in the circulation were started at different times before or after immunization. To elevate serum Ca^{2+} levels (by approximately 2 mequiv/l.), 400 µg of $CaCl_2$ (dihydrate, Merck) was injected intravenously, at 6 h intervals, a total of five times (each dose being approximately 1 mequiv/kg). To lower serum Ca^{2+}, porcine calcitonin (Armour, Lot K 423–079, obtained through Dr J. W. Bastian) was injected subcutaneously, 1 MRC unit per mouse, every 8 h, a total of three times. Groups of five mice were used.

Results were calculated in terms of multiples or fractions of average responses in experimental groups compared with the average response in untreated, immunized animals. In the case of the 48 h determinations, the elevation of Ca^{2+} levels, if initiated either before or 12 to 24 h after antigen administration ("early" or "late"), significantly inhibited responses; by contrast, if elevation of Ca^{2+} levels was started at the time of antigen administration, or within 6 h thereafter, the responses were stimulated. The effects of calcitonin were essentially the reverse of the effects obtained after Ca^{2+} elevation (in a subsequent test a 3·5-fold stimulation was obtained when calcitonin treatment was started after 18 h). Seventy-two hours after immunization, the enhancement of antibody formation resulting from Ca^{2+} elevation, at or shortly after the time of immunization, was even more striking (Fig. 1), but the suppressive effects, noted in assays 48 h after immunization, were no longer detectable. In fact, early or late modification of Ca^{2+} levels now showed some stimulatory effects.

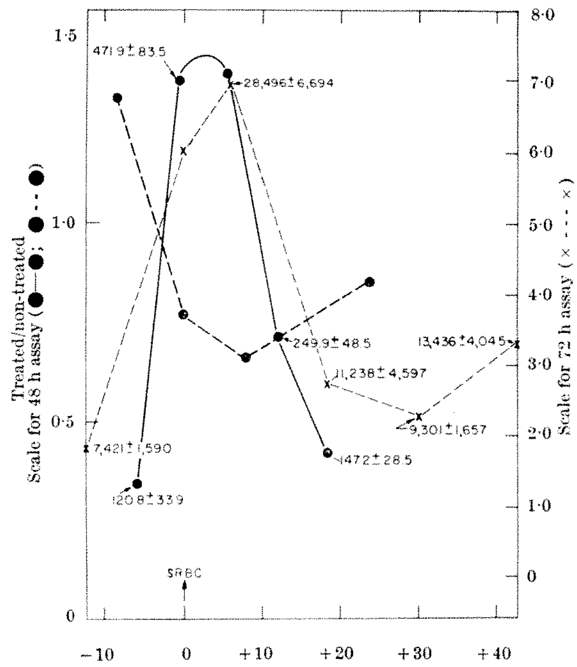

Fig. 1. The influence of $CaCl_2$ and calcitonin, administered at different times before and after immunization with SRBC, on the number of antibody forming spleen cells (AFC) in mice 48 h and 72 h after immunization. The results are given in terms of the ratio of average number of AFC in treated groups to the average number of AFC in the control group receiving SRBC only. Each group contained five CFW females; the figures adjacent to some of the points indicate average AFC/10^8 spleen cells ± *S.E.* ●——● and × - - - ×, $CaCl_2$ (400 µg/mouse intravenously every 6 h; five times). Control value for 48 h assay: 348·1 ± 12·0; for 72 h assay: 4,139 ± 912. ● — — — ●, Calcitonin (1 MRC unit/mouse subcutaneously every 8 h; three times).

The inhibitory effect of early (−6 h) Ca^{2+} elevation, detectable 48 h after immunization, was overcome by the administration of poly A·poly U, a known stimulator of antibody responses[25] if given at the time of antigen injection; poly A·poly U did not, however, increase the enhancement effect of Ca^{2+}.

The inhibitory effects of "early" and "late" Ca^{2+} elevation may be understood in terms of interference with the handling of the immunogen by macrophages on the one hand, with the interaction of lymphocytes with antigen, required for "driving" the antibody response[6], on the other. Similarly, the stimulatory effects of "early" and "late" calcitonin administration could be attributed to an increased permeability of macrophages and lymphocytes. What is difficult to explain, so far, is the stimulatory effect of Ca^{2+} elevation (and the reverse effect of Ca^{2+} depression), when the modification of Ca^{2+} levels is initiated at or shortly after the time of immunization. Perhaps the handling of an excessive and interfering amount of antigen is "shut off"; or perhaps the cells involved in the early events leading to antibody formation act more effectively. In view of the several cell types and many events involved in antibody formation, however, a conclusive interpretation of the modifying effects of elevated Ca^{2+} levels cannot be given.

Calcium ions influence several types of membrane-associated events, which may be involved in modifying immune responses. Ca^{2+} is important in regulating the deformability and viscosity of the membrane[7]; the plasma membrane becomes extremely rigid when the intracellular Ca^{2+} is raised[8]. Such events may affect endocytosis, which seems to play a part in antibody formation. Low extracellular Ca^{2+} increases the permeability of the cell membrane to various ions[9,10] and the resulting changes in cytoplasmic electrolyte levels may affect the activity of intracellular enzymes involved in antibody formation. Cytoplasmic Ca^{2+} levels have been recognized as the primary link in the general concept of stimulus-response coupling which embraces all the events between stimulation of the cell membrane (for example, by antigen) to the responses of the cell[11-14]. For example, histamine release from mast cells during the antigen–antibody reaction requires the presence of Ca^{2+} in the medium[15,16]. Ca^{2+} is also important in controlling the electrical excitability and membrane potential of cell membranes[17-19]; it influences complement-dependent reactions[20], and modifies membrane-associated enzymes, such as Mg-ATPase[21,22]. Finally, contacts among various cells are required for the activation of immune responses and Ca^{2+} is known to be important for the maintenance of cell junctions and communicability[23].

Further studies of the ways in which changes in Ca^{2+} levels may affect antibody formation by modifying membrane-associated events may aid significantly in the identification of critical membrane events in immune responses, and even permit a better manipulation—both in a positive and negative direction—of antibody formation. It may even be possible, through appropriate modifications of Ca^{2+} levels, to achieve some control over the direction of immune responses in terms of humoral antibody formation versus cell-mediated immunity.

Secretory Piece linked to IgM in Individuals deficient in IgA

THE IgA in exocrine secretions, by contrast with that in serum, is an 11S dimer containing an additional antigenic fragment, variously referred to as the transport piece, secretory piece or simply as the "piece" (ref. 1). Piece determinants, as detected by double diffusion precipitation in agar with a specific antiserum, occur in small amounts in the sera of up to 40 per cent of individuals with untreated adult coeliac disease, and in 9 per cent of healthy persons[2]. During a search for piece determinants I have examined the sera of thirty-four patients deficient in IgA. Thirty had hypogammaglobulinaemia or dysgammaglobulinaemia and had an increased susceptibility to infections. Four had other symptoms, but no history of repeated infections.

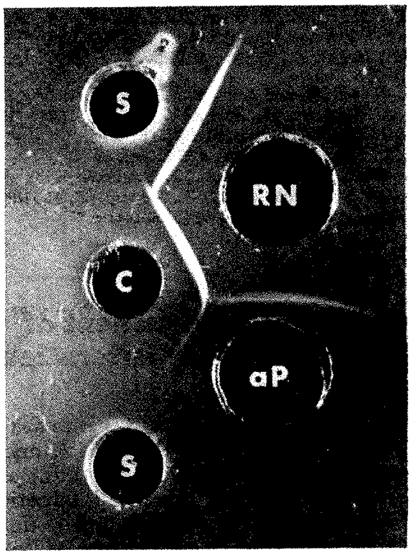

Fig. 1. Reaction with isolated colostral IgA (*C*) of the piece specific antiserum (*aP*), absorbed with normal human serum (*S*). A reaction of identity is given with the antibodies to piece determinants in an anti-secretory IgA antiserum (*RN*), provided by Dr R. W. Newcomb of Denver, Colorado.

A specific anti-secretory piece antiserum was prepared by injecting a preparation of human salivary IgA into a rabbit and absorbing the antiserum with whole human serum, with non-IgA-containing preparations of human salivary amylase and with an α_2 protein found in saliva[2]. Fig. 1 demonstrates the specificity of this antiserum. Three patients' sera gave a positive reaction with anti-piece antiserum, although two showed no evidence of alpha chain determinants in their sera and the third only a trace. The individuals suffered from recurrent infections —Table 1 lists their serum immunoglobulin levels. To detect small amounts of piece or alpha chain determinants, a sensitive haemagglutination-inhibition technique was developed. Colostral IgA, prepared by a slight modification of the method of Newcomb *et al.*[3], was coated on sheep erythrocytes using glutaraldehyde[4]. Using three minimum agglutinating doses of the anti-piece antiserum, exocrine IgA could be detected at a concentration of 0·4 μg/ml., and with a similar dose of an anti-alpha chain antiserum, monomer serum IgA could be detected at a

Table 1. IMMUNOGLOBULIN LEVELS (mg/ml.) IN THREE IgA DEFICIENT SERA

Serum	IgG	IgM	IgA	IgD
C. G.	2·5	2·24	< 0·03	< 0·01
G. K.	9·4	1·02	< 0·03	< 0·01
M. C.	2·3	0·15	< 0·03	< 0·01
Normal	6·8–23·5	0·32–2·4	0·81–6·3	< 0·01–2·2

Results were obtained by a single radial diffusion method.

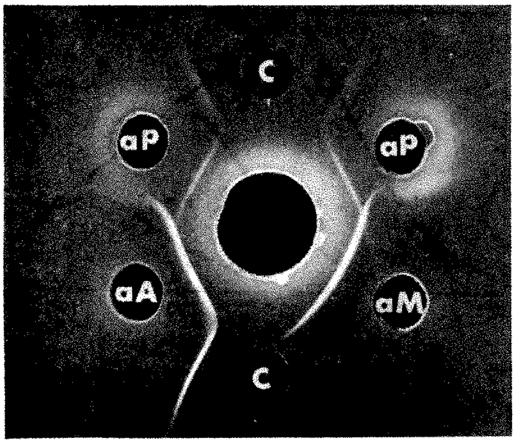

Fig. 2. Antigenic analysis of the pooled concentrated fractions of the first protein peak from gel filtration on 'Sephadex *G*-200' of the serum from a healthy individual (central well). *aP* = anti-piece antiserum; *aA* = anti-alpha chain antiserum; *aM* = anti-μ chain antiserum; *C* = isolated colostral IgA.

concentration of 0·2 μg/ml. The sera C. G. and G. K., at a dilution of more than 1 in 40, inhibited the agglutination of the colostral IgA coated cells by the anti-piece antiserum, but not that by an anti-alpha chain antiserum; the serum M. C. inhibited agglutination by both antisera to the same degree.

In the sera of individuals with adult coeliac disease and healthy individuals showing piece determinants, this activity is usually confined to the IgA region on electrophoresis, and to the fractions of the exclusion peak from gel filtration of serum on 'Sephadex *G*-200' (ref. 2). The haemagglutination-inhibiting activity has the same electrophoretic location and occurs in the retarded fractions of the first protein peak from the 'Sephadex' column, while the principal portion of the serum IgA was eluted in the second protein peak. Antigenic analysis of the first peak fractions containing this activity, from a healthy individual having an appreciable amount of piece determinants in the serum (Fig. 2), indicated that piece determinants in the fraction were linked to IgA, although a considerable portion of the IgA in the fraction was not so linked. On the other hand, there was a reaction of non-identity with the IgM-anti-μ chain line.

The sera of C. G. and M. C., deficient in IgA but containing piece determinants, were subjected to gel filtration on 'Sephadex *G*-200'. Piece determinant haemagglutination-inhibiting activity occurred only in the main fractions of the exclusion peak. Antigenic analysis of the pooled concentrated fractions of the exclusion peaks from the 'Sephadex *G*-200' gel filtration of these sera (Fig. 3) gave for each material a reaction of non-identity with IgA, and spurred with the IgM-anti-μ chain line, although clearly a considerable amount of IgM was present which did not contain piece determinants. Electrophoresis in agar of whole serum (G. K.) showed that the piece determinants had a similar distribution to the serum IgM.

Table 2. PIECE DETERMINANT HAEMAGGLUTINATION-INHIBITION TITRE AFTER PRECIPITATION OF SERUM IMMUNOGLOBULIN

		Immunoglobulin precipitated			
Sera		IgG	IgM	IgA	IgD*
IgA deficient	C. G.	45	2	—	50
	G. K.	60	2	—	50
Healthy	A.	80	55	4†	60
	E. S.	70	60	16†	90

* Anti-IgD added in antiserum excess.
† Anti-alpha chain antiserum added to the point of slight antigen excess.

Attempts were made to remove piece determinant haemagglutination-inhibiting activity by precipitation of the immunoglobulins from the IgA deficient sera, and from the sera of two healthy individuals, by specific anti-immunoglobulin heavy chain antisera, prepared in sheep by methods described by Rowe *et al.*[5] (Table 2). The activity was removed by precipitation of the IgM, but not of the IgG, in the IgA deficient sera; in the sera of the healthy individuals it was removed by precipitation of the IgA—but not of the IgM or IgG—or by the addition of anti-delta chain antiserum in antibody excess.

Some individuals with a deficiency of IgA have an excess of IgM in their secretions[6-8], although no evidence of linkage of this IgM to secretory piece was obtained by Brandtzaeg *et al.*[8]. Exocrine secretions from our three patients were not available, but the duodenal juice from another patient deficient in IgA was studied. This patient had no history of recurrent infections, and the juice showed no alpha chain determinants, but contained 7 mg/100 ml. of IgM and a trace of IgG. During gel filtration of this juice on 'Sephadex *G*-200', piece determinants were located by haemagglutination-inhibition in the IgM containing fractions of the exclusion peak, and after the fractions of this peak were pooled and concentrated, these determinants were assigned to the IgM by antigenic analysis in agar as in the experiment of Fig. 3. Again the larger proportion of the IgM did not seem to be so linked.

The association of IgM with secretory piece in individuals lacking IgA raises a number of questions. It has been suggested[9] that, in normal circumstances, secretory piece forms a primary non-covalent bond with exocrine IgA which is stabilized by the formation of disulphide bridges. The nature of the bond with IgM is unknown, but it could be formed similarly. The specimens we studied were too small to allow an elucidation of this problem and the amount of IgM linked to secretory piece represented

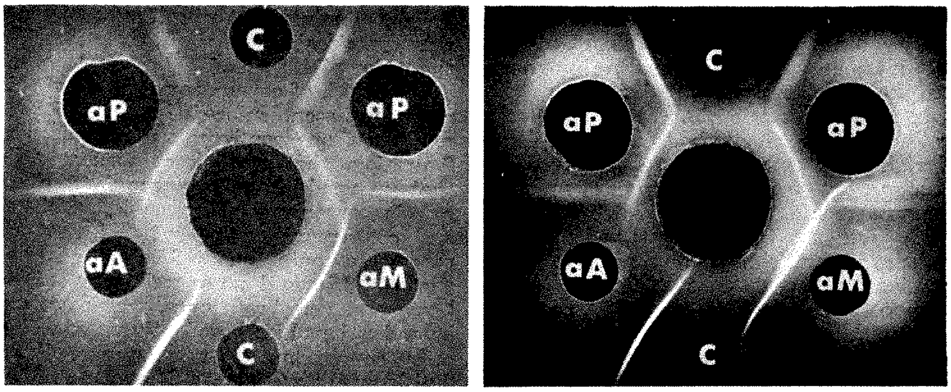

Fig. 3. Antigenic analysis of the pooled concentrated first peak fractions from the gel filtrations on 'Sephadex *G*-200' of two IgA deficient sera, M. C. (left) and C. G. (right). The pooled fractions are in the central well in each case, and the reagents around the peripheral wells are arranged as in Fig. 2.

only a small fraction of the IgM in each. Using more sensitive methods, it may well prove that the amount of secretory-piece-linked IgM is always small; it may, indeed, be dependent on the proportion of a sub-class of IgM in the secretions. The function of this additional determinant is unknown, but it may increase the resistance of exocrine IgA to digestion by proteolytic enzymes, and it may also do this for IgM.

I thank Professor P. G. H. Gell for use of the facilities of the Department of Experimental Pathology, University of Birmingham.

Natural Selection versus Gene Uniqueness

SMITH[1] has compared protein evolution with a popular word game. Just as the object of the game is to pass from one word to another by changing one letter at a time, so in the process of evolution one protein is changed to another by changing only one gene nucleotide at a time. As in the word game each change must result in an English word, so in protein evolution each nucleotide change must result in a viable protein.

I would point out, however, that it is not sufficient for each nucleotide change to result in only a viable protein—a better protein must be produced, such that natural selection would tend to favour it over the old protein.

Smith points out that, for evolution by natural selection to occur, functional proteins must form a continuous network which can be traversed by unit mutational steps without passing through non-functional intermediates. As a matter of fact, the protein network must have even a more stringent property, namely the possibility of traversing the network by unit mutational steps always proceeding to a more adaptive protein. Unless a mutation leads to a phenotype of greater selective value, a transition from the old phenotype would simply not be made. Thus when Smith asserts that his parameter f must be greater than 10^{-3}, he should be talking not about the fraction of viable proteins that can be derived by unit mutational steps, but about the fraction of proteins that represent improvements.

Although Smith gives the impression that he is disagreeing with Salisbury[2], and that a value of 10^{-3} for f is small, close examination reveals that the points Smith raises actually support Salisbury's contention. The value of f suggested by Smith means that an enormous number of unit mutational improvements are possible. If this is the case, the gene is far from unique. This was Salisbury's contention: the concept of evolution by natural selection and the concept of the uniqueness of the gene are incompatible.

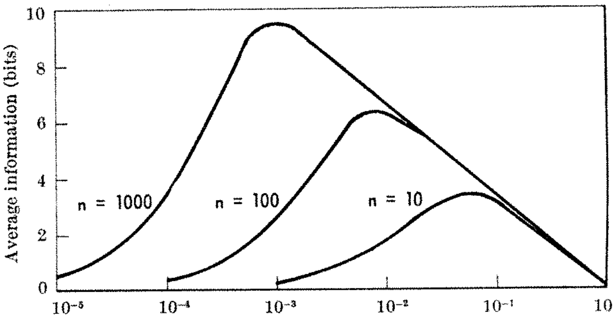

Fig. 1. Average information that can be transmitted into a species in 10^{12} to 10^{14} trials or fewer. The average information is plotted as a function of the fraction of sequences that represent better adapted phenotypes.

I have previously described this situation in terms of the amount of information that can be incorporated into the genetic message by the process of random mutation and natural selection[3]. The increasing adaptivity of a species of organism to its environment through an evolutionary process was viewed as a process of transmitting information from the environment into the species. The advantage of considering the problem as one of information transmission is that, in computing the expected amount of information incorporated into the genetic message, one simultaneously takes into account the effect of the probability of achieving an improvement, which is a monotonic increasing function of f, and the information added, which is a monotonic decreasing function of f.

Fig. 1 shows the average amount of information that can be transmitted into the genetic message in one evolutionary step. The average information is plotted as a function of f for various values of n, the number of nucleotides available for change. An evolutionary step is here defined as a sufficiently large number of trials (that is, births), perhaps as many as 10^{12} to 10^{14}. If an entire gene is available for change, then the $n = 1{,}000$ curve shows that a maximum amount of information of about 9·5 bits can be gained by the gene if $f \approx 10^{-3}$. If, on the other hand, only small sections of the gene are available for change—such as the active site—then the maximum amount of information is correspondingly smaller.

In a previous report[3] I have indicated how the expected information depends on the amount of grammatical structure, if any, that must be evolved along with the necessary phenotypic improvements. Calculations there show that, when a requirement for a grammatical structure is included, the maximum average information that can be transmitted into the genetic message is considerably smaller than that shown in Fig. 1.

A natural question to ask then is: where did all the information come from that is now in the gene? As Salisbury points out, even if only 10 per cent of the DNA represents real information, this still means something of the order of 10^8 bits.

We could, of course, say that all of this DNA does not really represent information in the sense that it only represents one configuration out of many possible configurations that could have occurred. This would mean that we would have to argue for the non-uniqueness of existing organisms. How could we then explain parallel and convergent evolution? If the eye, for example, represents only one of about 10^{10^6} possible forms that could have done as well, why is it that the invertebrate and vertebrate eyes, which are supposed to have been developed independently, seem to be so much alike?

In conclusion, after examining Smith's arguments, Salisbury's contention still seems to stand: the concept of evolution by random mutation and natural selection and the concept of the uniqueness of the gene are apparently contradictory. Further, if we should take the view that the gene is not unique, then we have to begin revising our present ideas of the phylogenetic tree in order to remove the concepts of convergent and parallel evolution.

Induction of DNA Polymerase in Mixed Lymphocyte Cultures

HISTOCOMPATIBILITY is frequently determined by serological typing of lymphocytes for HL–A alloantigens[1]. This method is restricted by the availability of specific antisera and may be hampered by undetected antigens[2]. There is, however, no restriction on the choice of antigenic determinants in mixed leucocyte culture reactions. When lymphocytes from the peripheral blood of two individuals are mixed and cultured together, the extent of stimulation seems to be a function of disparities in histocompatibility[4]. "One way stimulation" can also be studied by preventing replication of either set of lymphocytes by prior treatment with mitomycin C (ref. 5) or by X-irradiation[6]. The morphological observation of blastogenesis and measurements of the uptake of ^{3}H-thymidine into cellular DNA have been used to monitor stimulation, but they have deficiencies (see, for example, refs. 7, 8).

A more reliable parameter for quantitating the extent of DNA replication in mixed lymphocyte cultures may be to assay DNA polymerase activity, *in vitro*[10], in cultures containing lymphocytes from two unrelated individuals.

Lymphocytes were isolated from the blood of healthy volunteers by the method of Cooper[9]. The final preparation of lymphocytes was suspended at a concentration of $7\cdot5\times10^5$ cells per ml. in Eagle's MEM (Spinner modification) (GIBCO, Grand Island, NY), containing 20 per cent foetal calf serum, 1 per cent L-glutamine, penicillin (100 units per ml.) and streptomycin (100 μg per ml.). The cell suspensions were incubated at 37° C in 16 × 125 mm disposable plastic culture tubes. After incubation for the times indicated in Fig. 1, the cells were washed and centrifuged at 2,500*g* in 0·15 M KCl. The final cell pellet was disrupted by rapid freezing and thawing in 0·1 ml. of a solution made up of 20 per cent glycerol, 0·02 M potassium phosphate buffer (*p*H 7·4), 0·004 M reduced glutathione, and 0·001 M potassium EDTA. DNA polymerase activity was determined as previously described[10] using the entire broken cell suspension from each culture as an enzyme source.

The DNA polymerase activity of cultured human lymphocytes is shown in Fig. 1. Essentially no stimulation occurred when lymphocytes from only one individual were in culture (LA or JB, 1 ml, cultures). The slight increase in activity of JB lymphocytes might have resulted from an immunological reaction directed against a component added to the culture medium, for example penicillin, foetal calf serum or streptomycin[11]. When cells from both individuals were cultured together in the same tube (LA plus JB, 2 ml. cultures) however, the DNA polymerase activity was markedly stimulated to an extent greater than the sum of the two individual curves at any time after 36 h. The periodic fluctuation of DNA polymerase activity in the mixed cultures is significant and may reflect changes in the population dynamics of these partially synchronized cells. As previously shown, phytohaemagglutinin (PHA) added to lymphocyte cultures from a single individual results in an even greater increase of DNA polymerase activity (JB plus PHA)[10].

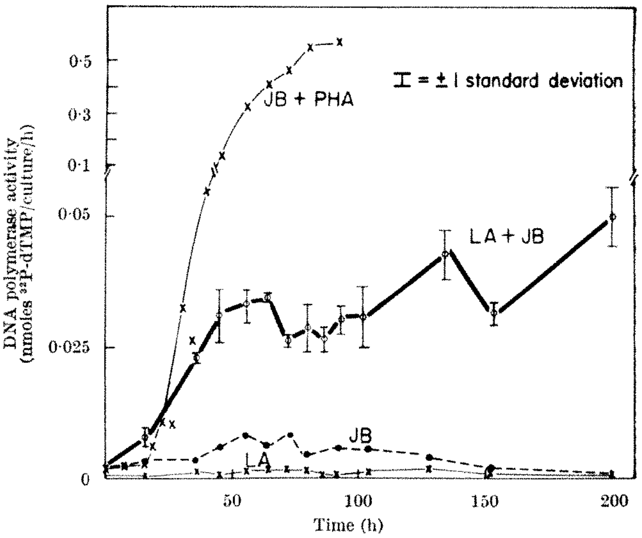

Fig. 1. Stimulation of DNA polymerase activity by lymphocyte interactions. All results were obtained from aliquots of lymphocytes from the two individuals (LA and JB) which were cultured simultaneously in triplicate in the presence and absence of PHA. Individual cultures contained 1 ml. suspensions of lymphocytes from LA or JB, while the mixed culture contained 1 ml. of cells from each of the individuals. In control experiments the activities of the cultures were proportional to the amount of cells. For example, 0·5, 1·0 and 2·0 ml. of a lymphocyte suspension which was cultured for 72 h had polymerase activity of 3, 5, and 8 pmoles, dTMP/culture/h; similar cultures incubated with (PHA) had a polymerase activity of 120, 248, and 500 pmoles, dTMP/culture/h, respectively. One ml. portions of lymphocytes from JB were incubated with 0·025 ml. of PHA–M (General Biochemicals, Ohio). DNA polymerase activity was measured as the incorporation of an appropriately labelled deoxynucleotide into an acid-insoluble product. The reaction mixture in a total volume of 0·3 ml. is the following: 25 μmoles Tris–maleate buffer, *p*H 8·0; 3 μmoles $MgCl_2$; 1 μmole KCl; 0·3 μmole β-mercaptoethanol; 25 nmoles each of dATP, dCTP, dGTP, and 10 nmoles of [α-^{32}P]-dTTP (about 5×10^4 d.p.m. per nmole) (International Chemical Nuclear, City of Industry, California); 255 nmoles of "activated" calf thymus DNA and 0·1 ml. of the final lymphocyte suspension. Incubation was for 1 h at 37° C and incorporation was determined after washing the acid-insoluble material by centrifugation[9]. Incorporation without incubation was 1·0 pmoles dTMP/culture.

In other studies we have presented evidence that as an index of lymphocyte stimulation, DNA polymerase is a reliable parameter for measuring the replicating response of lymphocytes to a mitogenic stimulus[12]. Because DNA polymerase activity is assayed *in vitro* it is not affected by concentration of metabolites in the cultures. The sensitivity of this assay is, for the most part, limited only by the specific activity of the labelled deoxynucleoside triphosphate precursors. With ^{32}P or ^{14}C-labelled deoxynucleoside triphosphates as precursors, DNA polymerase activity can be determined on the same cultures which previously incorporated ^{3}H-thymidine into cellular DNA. Assays of DNA polymerase activity and thymidine incorporations are not only supportative but are also useful in studying their interrelationships.

Phytohaemagglutinin, an extract of the red kidney bean, *Phaseolus vulgaris*, causes a similar transformation, though the extent of the response is much greater[13]. Whether or not the effect of phytohaemagglutinin is the same as that resulting from cell interactions in the mixed lymphocyte culture reaction is unknown. The increase in DNA polymerase activity in both phenomena could, however, result from an increased requirement for DNA polymerase activity associated with the transformation of well differentiated lymphocytes into actively replicating lymphoblasts. This transformation may be relevant for the expression of the immunologic properties of these cells.

Molecular Weight and Chain Length of Rabbit Reticulocyte rRNA

THE molecular weight of mammalian ribosomal RNA has been the subject of various studies. Estimates of molecular weight of RNA by sedimentation and viscosity from Jensen sarcoma[1], liver[2] and HeLa cell[3] ribosomes are between 0·58 and 0·67 × 10^6 daltons for the small subunit and between 1·64 and 1·9 × 10^6 daltons for the large subunit. Estimates made by measuring the length of RNA molecules are 0·86 and 0·83 and 1·73 and 1·61 × 10^6 daltons for the small and large subunits of erythroblast and HeLa cell rRNA when compared with the length of *Escherichia coli* rRNA[4]. Estimates made by exonuclease digestion, when compared with *E. coli* RNA, give values of 0·4 and 0·8 × 10^6 daltons for the small and large subunits of HeLa cell rRNA[5]. I now present data which suggest that the RNA from rabbit reticulocytes consists of two main subunits of molecular weight 0·65 and 1·53 × 10^6 daltons and that in most conditions of isolation there is a small molecule of RNA associated in equimolar amounts with the large RNA subunit.

Reticulocyte polyribosomes were isolated in the absence of magnesium and the ribosomal subunits fractionated on sucrose gradients after treatment with EDTA[6]. Narrow cuts from the large and small ribosomal subunit peaks were taken to minimize cross-contamination. RNA was extracted from the ribosomal subunits using guanidinium chloride[7,8]. Polyacrylamide gel electrophoresis of the RNA revealed little cross-contamination between the large and small subunits. Periodate oxidation and condensation with isoniazid were performed as described previously[7]. Excess isoniazid was removed by chromatography on 'Sephadex *G*-75'.

Previous experiments have shown the usefulness of this method in determining molecular weights by yielding a value of 27·0 × 10^3 daltons for *E. coli* transfer RNA, in agreement with values of 24–27 × 10^3 daltons found by sequence analysis[7]. Midgley[8] has confirmed this finding and extended it to calculate the molecular weight of *E. coli* tRNA and 16S and 23S rRNA as 24 × 10^3 and 0·53 and 1·0 × 10^6 daltons, in good agreement with measurements by sedimentation and viscosity[9,10].

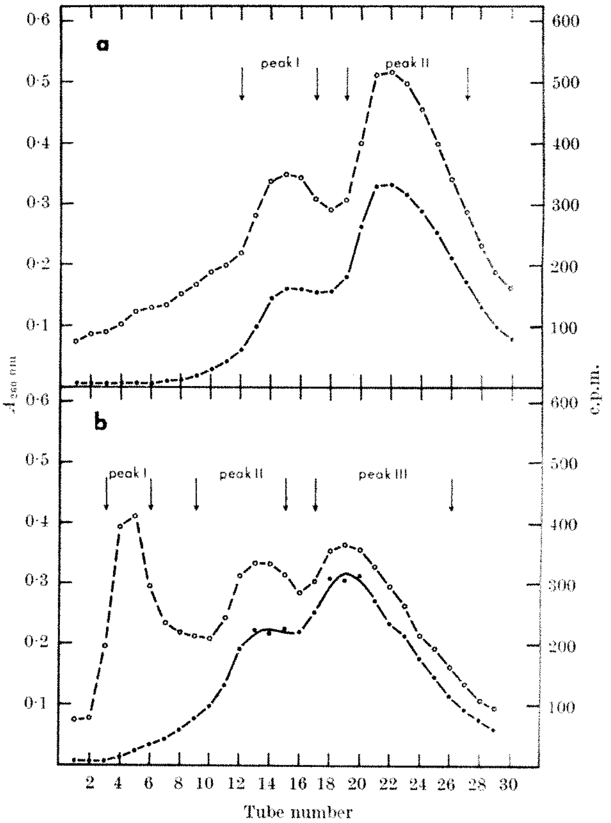

Fig. 1. Sucrose gradients of RNA fractions after periodate oxidation and condensation with isoniazid. All gradients were 17 ml. linear 5–20 per cent in sucrose in 0·1 M sodium acetate (*p*H 5·0). Centrifugation was at 25,000 r.p.m. at 4° C in a Spinco 'SW 25·3' swinging bucket head. Time of centrifugation was 20 h for (*a*) and 18 h for (*b*). (*a*) Untreated RNA from the large ribosomal subunit. (*b*) RNA from the large ribosomal subunit heated in 0·5 per cent sodium dodecyl sulphate in 0·1 M sodium acetate at 60° C for 10 min. 0·1 ml. of each fraction was diluted with 0·9 ml. of 0·1 M phosphate (*p*H 7·0) for measurement of absorbance at 260 nm; 0·5 ml. of these fractions was mixed with 4 ml. of a scintillation mixture containing 20 per cent Beckman 'BBS 3' solubilizer and 80 per cent of 0·5 per cent 2,5-diphenyloxazole and 0·5 per cent 1,4-*bis*-(4-methyl-5-phenyloxazol-2-yl)benzene in toluene. The efficiency of counting tritium in this system was 19·1 per cent for (*a*) and 19·7 per cent for (*b*). Areas marked were collected by precipitation with 2 volumes 95 per cent ethanol, with the addition of 1·0 mg of carrier RNA for (*b*), I, for further analysis. ●—●, Absorbancy; ○ - - - ○, radioactivity.

The low values for the molecular weight of the rRNA isolated from ribosomal subunits compared with the values obtained from sucrose gradient fractionated total rRNA (Table 1) indicated that more than one molecule of RNA was present in the large subunit, most probably as a small molecule of RNA bound to the 28S RNA. To determine if this were the case, guanidinium chloride extracted RNA from the ribosomal subunits was heated in 0·5 per

Table 1. MOLECULAR WEIGHT OF RNA FROM 40S AND 60S RIBOSOMAL SUBUNITS TREATED IN DIFFERENT WAYS BEFORE AND AFTER SUCROSE GRADIENT SEDIMENTATION

Treatment	Molecular weights of RNA (daltons × 10^{-6}) Small subunit Before fraction-ation	Small subunit Main 18S peak after fraction-ation	Large subunit Before fraction-ation	Large subunit Main 28S peak after fraction-ation
None	0·432	0·688	0·742	1·18
0·5 per cent sodium dodecyl sulphate at 60° C before periodate oxidation and isoniazid reaction	0·368	0·650	0·755	1·53
7 M urea after isoniazid reaction	0·473	0·686	0·810	1·13
*p*H 3·0 after isoniazid reaction	0·475	(Not measured)	0·834	1·13
* Total ribosomes with guanidinium chloride followed by sucrose gradient fractionation	—	0·66	—	1·38
* Total ribosomes with 0·5 per cent sodium dodecyl sulphate at 37° C followed by sucrose gradient fractionation	—	0·79	—	1·48

* From ref. 14.

Molecular weights of RNA were calculated by estimating the number of grams of periodate oxidized RNA which reacted with one mole of isoniazid. RNA was estimated by its absorption at 260 nm using an extinction coefficient of 23 for a concentration of 1 mg/ml. in a 1 cm cell.

cent sodium dodecyl sulphate in 0·1 M sodium acetate (*p*H 5·0) at 60° C for 10 min and then oxidized and condensed with isoniazid. Other samples of guanidinium chloride isolated RNA from the ribosomal subunits were oxidized and condensed with isoniazid and then treated with 7 M urea in 0·1 M sodium acetate (*p*H 5·0), and 0·1 M sodium acetate–HCl (*p*H 3·0) for 15 min at 0° C. Sodium dodecyl sulphate releases a "6S" RNA from HeLa cell 28S rRNA[11]; 7 M urea destroys hydrogen bonding[4]; while titration of RNA to *p*H 3·0 readily breaks down hydrogen bonding in RNA and effectively reveals "hidden breaks" caused by nuclease action[12].

Fig. 1 shows sucrose gradient analyses of control and sodium dodecyl sulphate treated RNA coupled with ^{3}H-isoniazid. The profiles of the 7 M urea and *p*H 3·0 treated RNA were identical in all respects with the control. Table 1 estimates the molecular weight of the RNA fractions before and after sucrose gradient fractionation. The sodium dodecyl sulphate removed a small RNA of molecular weight less than 60,000 daltons from the 28S RNA isolated from the large ribosomal subunit. Neither the *p*H 3·0 nor the 7 M urea treatment released this RNA and the RNA after these treatments had essentially the same estimated molecular weight as the control. The change in the molecular weight of the 18S RNA from the small subunit on sucrose gradient fractionation is independent of the treatment of the RNA and may reflect contamination by a small amount of tRNA. That the release of a "6S" molecule from the 28S RNA is specific and not the result of degradation can be demonstrated by end group analysis after enzymic digestion. Fig. 2 illustrates radio paper electrophoretograms of pancreatic ribonuclease and ribonuclease T_1 digests of 28S RNA isolated from sucrose gradients of control and sodium dodecyl sulphate treated RNA. It is clear that while the control 28S RNA has two different end groups with sequences -pGpU and -GpCpU (unpublished results), the sodium dodecyl sulphate treated 28S RNA has the sequence -pGpU and the "6S" RNA has the sequence -pGpCpU. No difference was detected between the 18S RNA end groups from any of the treatments; one sequence, -pUpA, is found.

Because the chain length determinations agree very well with the best estimates of molecular weight by physical methods I conclude that the reticulocyte 18S and 28S ribosomal RNAs are single chain molecules with molecular weights of $0·64 \times 10^{6}$ and $1·5 \times 10^{6}$ daltons respectively. The lengths measured by Granboulan and Scherrer[4] may be explained by assuming that the treatment with 7 M urea does not break down the hydrogen bonded helical loops and that there is a different percentage of loops in the two subunits[13].

It is very difficult to reconcile my results with those of Riley[5]. The presence of a small molecule attached to the 28S RNA would cause an alteration in the initial slope of his experiments. The "6S" molecule found here would double the slope up to 12 per cent degradation in saturating enzyme conditions. Riley's finding that rapid isolation of RNA increases its apparent molecular weight and that 45S RNA, which has sequences of both 18S and 28S RNA, seems to have a molecular weight the same as 18S RNA, strongly indicates that the techniques he has used for RNA isolation may have led to some degradation of the RNA. Until his method is rigorously checked using denatured tRNA as a standard and alternative methods for RNA isolation, it is difficult to assess the validity of the exonuclease technique for determining molecular weights for RNA.

This work was supported by a grant from the US National Institutes of Health. I thank Mr O. F. Peter

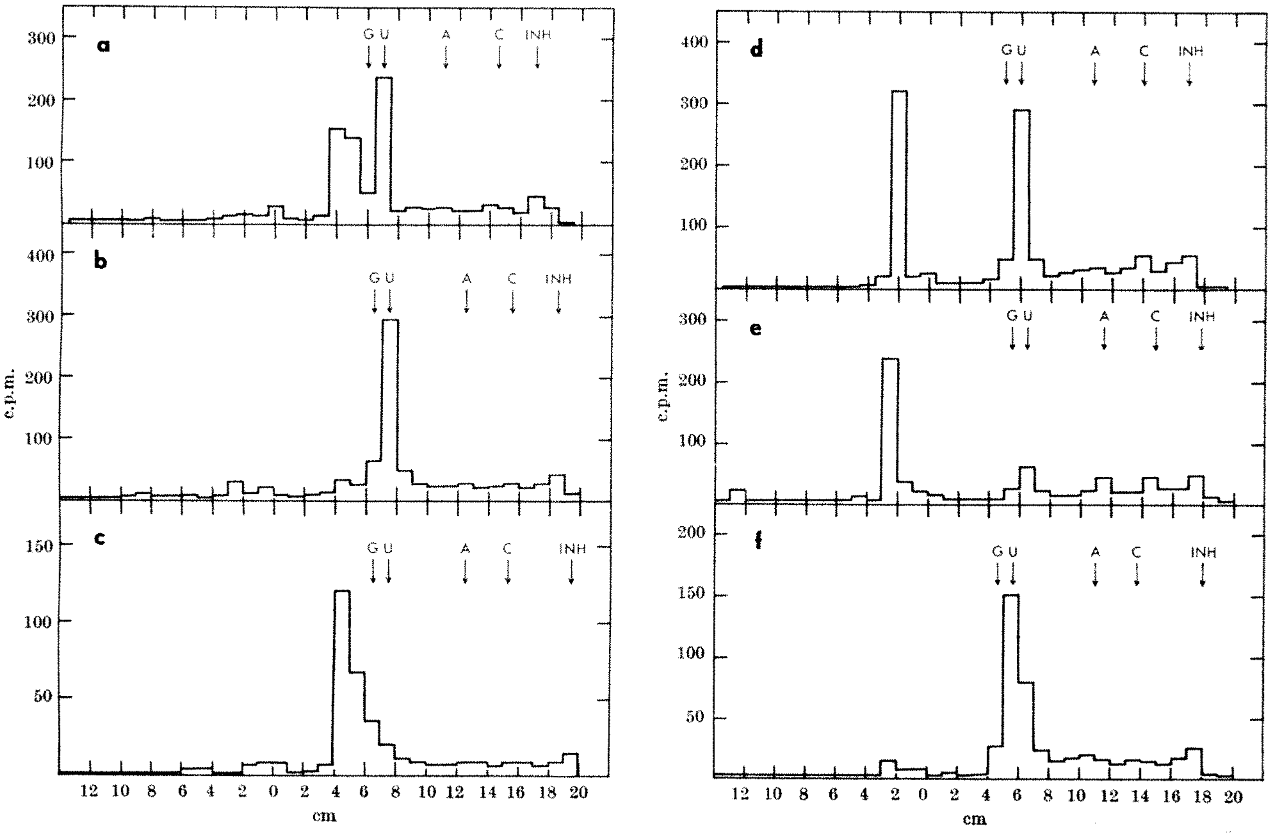

Fig. 2. Paper electrophoresis of pancreatic ribonuclease and ribonuclease T_1 digests of ^{3}H-isoniazid coupled RNA from various RNA fractions. Digestion and electrophoresis in 0·1 M triethylammonium formate (*p*H 3·0) were performed as described previously[4]. The paper was cut into 1 cm strips and moistened with water and either a dioxane scintillator[4] or the Beckman 'BBS3' toluene scintillator mixture added as described for Fig. 1. Counting efficiency with both systems was close to 19 per cent for tritium. (*a*)–(*c*) are ribonuclease T_1 digests, and (*d*)–(*f*) pancreatic ribonuclease digests. (*a*) and (*d*), untreated large ribosomal subunit RNA from peak II, Fig. 1 (*a*). (*b*) and (*e*) RNA heated in 0·5 per cent sodium dodecyl sulphate from peak III, Fig. 1 (*b*). (*c*) and (*e*) RNA heated in 0·5 per cent sodium dodecyl sulphate from peak I, Fig. 1 (*b*).

Intergeneric Transfer of a β-Lactamase Gene between *Ps. aeruginosa* and *E. coli*

THE transfer of antibiotic resistance genes between strains of enteric bacteria by cell-to-cell contact was first detected[1] in 1959, and much effort has now been directed towards the understanding of this genetic process, particularly in relation to the ecology of man and his domestic animals[2-4]. It is now clear that the problems raised by this phenomenon are world-wide, and the recent publication of the Swann report[5], with its recommendations for the restriction in the use of antibiotics in animal husbandry, has also underlined many gaps in our knowledge. One of these is undoubtedly an understanding of the range of bacterial species that can accept antibiotic resistance genes by cell-to-cell contact and harbour the *R*-factors involved. We report here that antibiotic resistance markers, particularly for resistance to carbenicillin, can be transferred freely between strains of *Pseudomonas aeruginosa* isolated from burns, and various enteric bacteria.

Lowbury and his colleagues[6] have recently reported the isolation of a series of carbenicillin resistant strains of *P. aeruginosa* from burns. Preliminary evidence showed that the strains produced a β-lactamase but no attempt was made to characterize the enzyme(s) further. What we have found is that two of the strains isolated by Lowbury (1822 and 3425) produce a β-lactamase indistinguishable in properties from an enzyme commonly found in strains of enteric bacteria expressing *R*-factor-mediated resistance to penicillin, and that the genes responsible for the synthesis of this enzyme can be transferred from both the *Pseudomonas* strains to *E. coli* K12 by cell-to-cell contact.

The β-lactamase synthesized by strains 1822 and 3425 was examined in broken cell preparations by irradiating exponentially growing cultures of the strains in question at a density of about 1·0 mg dry weight organisms/ml. in a 60 W ultrasonic disintegrator at 25,000 Hz for 2·5 min. Disruption in these conditions caused about a four-fold increase in enzyme activity, and the specific enzyme activity of such broken-cell preparations was about 80 enzyme units/mg dry weight of original unbroken cells, measured with benzyl penicillin as substrate.

To identify the type of enzyme synthesized by *Ps. aeruginosa* strains 1822 and 3425, broken-cell preparations were examined for their relative rate of hydrolysis of a range of penicillin and cephalosporin substrates. These experiments suggested that the strains did not synthesize a β-lactamase of the type previously examined[7] and commonly found in *Pseudomonas* strains, nor of the type synthesized by *Ps. aeruginosa* strain Dalgleish[8,9], but that the enzyme was most similar to that isolated and purified from *E. coli* carrying the *R*-factor R_{TEM} (refs. 10 and 11). To examine this further, the substrate profile of broken cell preparations of *Pseudomonas* strains 1822 and 3425 was compared with semi-purified enzyme preparations from *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$), from *Ps. aeruginosa* strain 1114 (a strain known to synthesize an enzyme indistinguishable from that described in *Ps. pyocyanea* NCTC 8203: refs. 7 and 9) and from *Ps. aeuruginosa* strain Dalgleish against benzylpenicillin, ampicillin, cephaloridine, cephalexin and carbenicillin as substrates. The profiles of these six preparations are shown in Table 1 and it seems clear that both strains 1822 and 3425 form an enzyme indistinguishable, on these grounds, from the enzyme synthesized by *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$), but quite different from the enzyme of *Ps.* strains 1114 and Dalgleish.

Table 1. SUBSTRATE PROFILES OF β-LACTAMASE FROM *Pseudomonas aeruginosa* STRAINS 1114, 1822, 3425, DALGLEISH AND FROM *Escherichia coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$)

* Arbitrary value of 100 for the rate of hydrolysis of benzyl penicillin.

The β-lactamase studied by Abraham and his colleagues in *Ps. pyocyanea* NCTC 8203 could be induced more than fifty-fold by growing the culture for about 3·5 h in the presence of 5 mg benzyl penicillin/ml.[7], and this behaviour was also found with Lowbury's strain 1114. By contrast, the enzyme from strains 1822 and 3425 (like that from *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$) (refs. 10 and 11)) was rigidly constitutive and neither growth in 5 mg benzyl penicillin/ml. nor growth in the same concentrations of ampicillin, cephaloridine or carbenicillin altered the rate of enzyme synthesis. To this extent, therefore, the synthesis of the β-lactamase by strains 1822 and 3425 was more similar to β-lactamase synthesis in *E. coli* than to synthesis in *Ps. aeruginosa* strain 1114.

The purification of the enzyme from *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$) in the past[11] has allowed specific antisera to this enzyme to be raised in rabbits, and it was already known that this antiserum was capable of neutralizing the β-lactamase against which it was prepared by about 60 per cent, but that the serum had no effect on the activity of enzyme preparations from *Pseudomonas* strains 1114 and Dalgleish[9]. Accordingly this serum was used to examine the enzymes from strains 1822 and 3425 in the hope that it might confirm the similarity between these enzymes and that of *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$) that was implied by the substrate profile determinations described above. About 50 units of enzyme in a series of flasks was treated with an increasing quantity of antiserum (constant antigen titration) by the method described previously to study a similar interaction between staphylococcal exo-penicillinase and anti-staphylococcal penicillinase serum[12,13], and Fig. 1 shows the results obtained with various enzyme preparations. The enzymes from strains 1114 and Dalgleish were unaffected by the addition of antiserum (Fig. 1*d*, *e*), but the enzymes from strains 1822 and 3425 were neutralized to some extent by the serum (Fig. 1*b*, *c*) and the neutralization curves obtained were indistinguishable from that observed from the interaction of the serum with enzyme from *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$) (Fig. 1*a*, *b*, *c*).

To confirm the similarity of the enzymes from strains 1822 and 3425 with the enzyme from *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$), crude enzyme preparations made by centrifuging broken-cell preparations of the strains in question were subjected to electrophoresis in starch gels prepared in borate

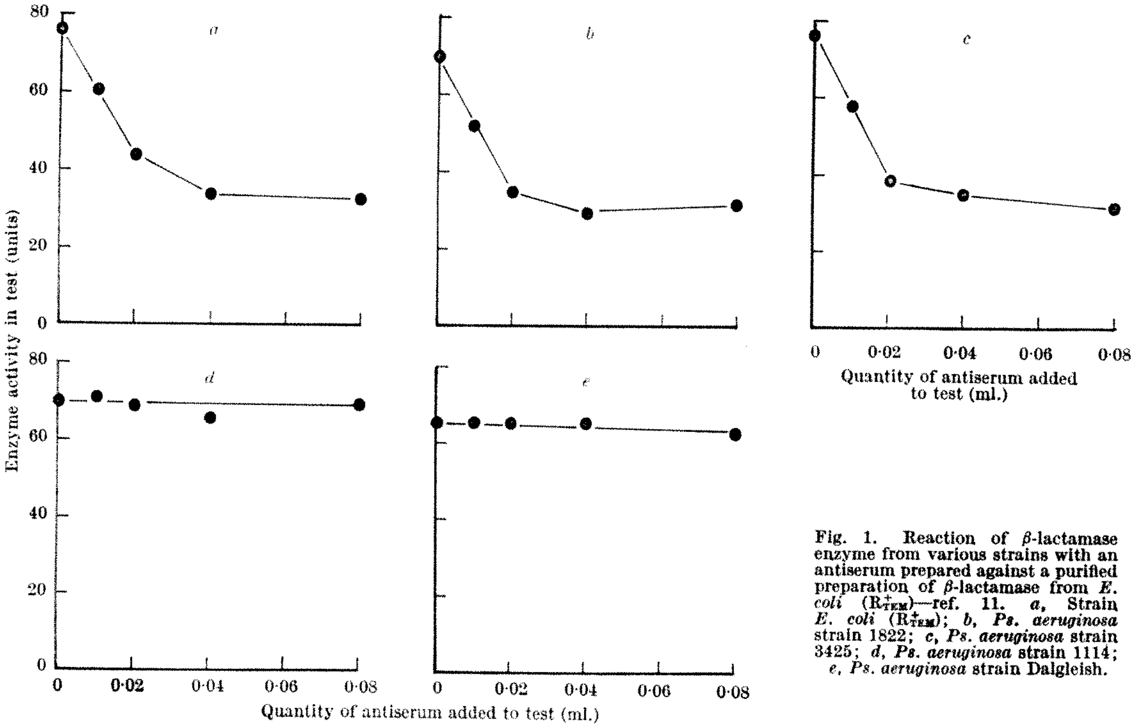

Fig. 1. Reaction of β-lactamase enzyme from various strains with an antiserum prepared against a purified preparation of β-lactamase from *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$)—ref. 11. *a*, Strain *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$); *b*, *Ps. aeruginosa* strain 1822; *c*, *Ps. aeruginosa* strain 3425; *d*, *Ps. aeruginosa* strain 1114; *e*, *Ps. aeruginosa* strain Dalgleish.

buffer, *p*H 8·5 (ref. 14). Once again the behaviour of the enzyme from *E. coli* and from *Ps. aeruginosa* strains 1822, 3425, 1114 and Dalgleish was compared. The gels were run in a potential gradient of 16 V/cm for 2·5 h and the location of the penicillinase detected by spraying the gels with a solution of 30 mg benzyl penicillin/ml. of 0·1 M Na_2HPO_4/KH_2PO_4 buffer, *p*H 5·9, containing 0·12 M KI and 0·016 M iodine[15,16]. The mobilities of the various enzyme preparations (Table 2) showed that the enzymes from strains 1822 and 3425 were indistinguishable from that of *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$) but different from those obtained with the enzymes from strains 1114 and Dalgleish. The combination of similar substrate profile, antiserum neutralization curves and electrophoretic mobility makes it extremely likely therefore that the enzyme synthesized by *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$)—and also by many other strains of enteric bacteria carrying *R*-factors—is identical to that synthesized by *Ps. aeruginosa* strains 1822 and 3425.

The detection of an enzyme in *Ps. aeruginosa* strains 1822 and 3425 that is commonly *R*-factor-mediated in enteric bacteria suggests immediately that there may be an intergeneric gene transfer of this type of β-lactamase gene between *Ps. aeruginosa* and *E. coli*. Furthermore, this possibility is strengthened by the fact that Lowbury and his collaborators[6] reported that β-lactamase production can be "purged" from *Ps. pyocyanea* strains 1822 and 3425 by growth in acriflavine (an attribute of some extrachromosomal genetic elements similar to *R*-factors[17]) and by the reports[18,19] that *R*-factor transfer can occur, albeit at low efficiency, and under rather poorly specified conditions, between pseudomonads and various enteric bacteria. The transferability of the β-lactamase gene in *Ps. aeruginosa* strains 1822 and 3425 was investigated by the plate method of Lee and Richmond[20]. The donor culture was mixed with the recipient *E. coli* strain at a multiplicity of one donor/1,000 recipients and selection for transfer achieved by a combination of overlaying the cells on the agar with a solution of 50 μg ampicillin/ml. and then growing the cultures anaerobically in a modified Makintosh/Fildes jar. These experiments showed that these donor strains of *Pseudomonas* could transfer their β-lactamase genes to the *E. coli* K12 recipient, strain 1822 giving a transfer frequency of 1 : 10^4 and strain 3425 giving about 1 : 10^5. Examination of the type of enzyme synthesized by the *E. coli* recipients that have received the β-lactamase gene from *Pseudomonas* showed that the enzyme was indistinguishable, on the basis of substrate profile, from the enzyme synthesized by *E. coli* ($\mathrm{R}^{+}_{\mathrm{TEM}}$) (Table 3). Furthermore, the antibiotic resistance patterns of the *E. coli* strains that had received the lactamase genes in these experiments showed that all the cells had also received determinants conferring resistance to tetracycline and to neomycin and kanamycin.

The linked transfer of the β-lactamase, tetracycline resistance and kanamycin/neomycin resistance genes in these experiments suggested that the donor pseudomonads may be carrying an *R*-factor of the type usually found among enteric bacteria. To confirm that the gene transfer from these donor strains was by cell-to-cell contact and not by transduction, the rate of gene transfer on mixing donor and recipient populations was compared with the rate of transfer obtained when a culture filtrate from the donor culture was mixed with the recipient cells. The filtrate was prepared by taking the culture supernatant obtained by centrifuging a whole culture at 5,000*g* for 15 min and filtering it through a membrane with pore size

* Arbitrary value for the rate of hydrolysis of benzyl penicillin.

capable of passing phage particles but of retaining any intact bacteria. Because gene transfer could not be detected using such filtrates (implying a frequency of transfer at least 10^5 smaller than obtained with cell–cell mixtures) it seems highly probable that this form of intergeneric gene transfer occurs by cell-to-cell contact.

Apart from the clinical importance of intergeneric transfer of this type, as was stressed by Lebek[18], the survival and effective functioning of the β-lactamase gene in two such dissimilar organisms are of great interest. Taxonomists have long separated Pseudomonads and the enteric bacteria on the grounds of their cultural characteristics, and a recent comparison between *Ps. aeruginosa* and *E. coli* using a comparison of 134 taxonomic characters in an Adansonian classification has shown that these species show a "similarity" (S-value) of only 35 per cent against values of 93 per cent or higher for two strains of *E. coli*[21]. Furthermore, the moles per cent G+C values for the total DNA of *Ps. aeruginosa* (64 per cent) are markedly different from that of *E. coli* (51 per cent)[22]. In short, therefore, one has here another example of the penetration of the gene pool of two widely different species of bacteria by a common extrachromosomal genetic element. Other examples of this phenomenon that have been reported include the transfer of *R*-factors from *E. coli* to *Salmonella* and to *Proteus* spp. as well as to *Serratia marcescens* (see ref. 23 for a review). In all these cases the phenotypic characters of the species involved have more in common than is the case with *E. coli* and *Ps. aeruginosa*. In practical terms, the intergeneric gene transfer of the type described here may mean that many genes, particularly those conferring resistance to antibiotics, that are usually encountered among the Enterobacteriacae may also occur among strains of *Ps. aeruginosa* and vice versa.

We thank Dr Edward Lowbury and his colleagues for giving us the strains we investigated, and for helpful discussions; Glaxo Laboratories, Ltd, for gifts of benzyl penicillin, cephaloridine and cephalexin; and Beecham Research, Ltd, for gifts of ampicillin and carbenicillin. The work was supported by the award of a postgraduate CAPS award to R. B. S. jointly by the Science Research Council and Glaxo Research, Ltd, and of a grant-in-aid from the Royal Society to M. H. R. for the purchase of a recording spectrophotometer.

Enzymatic Binding of Valine to the 3' End of TYMV-RNA

THE genetic material of turnip yellow mosaic virus (TYMV) comprises RNA of molecular weight approximately 2×10^6, and of sedimentation constant close to 25S. In the presence of cell-free extracts and ATP, this RNA can interact with one amino-acid, valine, which becomes attached to its terminal nucleoside, an adenosine residue, by an ester linkage.

Table 1. REQUIREMENTS FOR THE BINDING OF VALINE TO TYMV-RNA

Conditions	^{14}C-Valine bound (pmoles)
Complete system	37
– Proteins	< 1
– ATP	< 1
– TYMV-RNA	< 1

The incubation mixtures contained in a final volume of 200 µl. were: 10 µmoles of Tris-HCl (*p*H 7·4), 1 µmole of $MgCl_2$, 0·2 µmole of DTT, 3 nmoles of ^{14}C-valine (125 mCi/mmole) and—where indicated—100 µg of *E. coli* proteins, 0·2 µmole of ATP and 50 pmoles of TYMV-RNA. After incubation for 30 min at 32° C, the reactions were stopped by addition of 5 per cent cold TCA and the resulting precipitates extensively washed on 'Millipore' filters and counted in Bray's solution[2]. *E. coli* (MRE 600) 105,000*g* supernatant was chromatographed on DEAE-cellulose to remove nucleic acids; the protein fractions eluted between 0·1 and 0·25 M KCl in 0·01 M Tris-HCl (*p*H 7·4) were used in these experiments. TYMV-RNA was stored at – 20° C as a precipitate in ethanol in the presence of bentonite.

The virus was isolated from the leaves of Chinese cabbage (*Brassica chinensis*) and its RNA extracted by phenol[1]. When this RNA was incubated with ^{14}C-valine, ATP and bacterial or yeast cell-free extracts devoid of endogenous RNA and free amino-acids, ^{14}C-valine was recovered with viral RNA. Table 1 shows the requirements of this reaction. The valine bound to TYMV-RNA was not removed by cold acid treatment (5 per cent trichloroacetic (TCA) or perchloric acid), was precipitated with the RNA by 1 M NaCl; it was, however, rapidly liberated at *p*H 10 or by hot TCA. Moreover, GTP, CTP and UTP did not promote this transfer, and at high concentrations these nucleotides inhibited the ATP-dependent reaction. Binding of valine and of other amino-acids to TYMV-RNA has been previously described by others[3], but with different results.

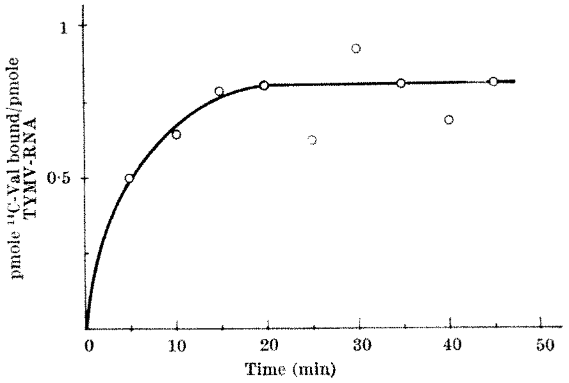

Fig. 1. Kinetics of valine binding to TYMV-RNA. The experimental conditions were as described in Table 1. At the times indicated, aliquots were removed and the radioactivity bound to cold TCA precipitated material was determined as already described.

We have followed the kinetics of valine binding to cold TCA precipitable material (Fig. 1). Maximum binding was at 15 min, and at this saturation point, 0·8 molecule of valine was bound per molecule of RNA (of mol. wt. 2×10^6). Using various batches of RNA stored for different periods of time, it was observed that this ratio fluctuated between 0·3 and 0·8.

Fig. 2 shows the behaviour of the charged RNA after centrifugation in sucrose gradients. About 80 per cent of the valine was recovered with 25S RNA, and the remaining 20 per cent was bound to slowly sedimenting material. On 'Sephadex G-100', in the presence or absence of 8 M urea, and at room temperature, about 75 per cent of the valine emerged in the void volume, and 25 per cent was retarded. The presence of $A_{260\ \mathrm{nm}}$ absorbing material closer to the top of the gradient (Fig. 2) and its absence in non-incubated RNA (not shown) proved that, during incubation, some degradation of TYMV-RNA occurred. TYMV-RNA treated at *p*H 10 to 11 is known to split into fragments sedimenting at about 5S (refs. 4 and 5).

To determine whether other amino-acids interacted similarly with this viral RNA, TYMV-RNA was incubated with a mixture of fifteen ^{14}C-labelled amino-acids (reconstituted hydrolysate of *Chlorella*); the radioactive material retained by the RNA was released by alkaline hydrolysis and analysed by thin-layer chromatography; valine was the only amino-acid recovered.

When charged TYMV-RNA was incubated for 1 h at room temperature in the presence of 0·5 M Tris-HCl (*p*H 8·2), and the radioactive material analysed by paper chromatography, valine and one other compound—identified chromatographically with Tris valyl-amide—were observed. The second compound must result from aminolysis of the bond between valine and TYMV-RNA by the NH_2 group of Tris. Identical results were obtained with valyl-tRNA of *E. coli* treated in the same conditions; O-methylvaline did not undergo aminolysis. The carboxyl group of valine bound to TYMV-RNA seems therefore to have become highly reactive, and probably forms an energy-rich ester bond. That the amino group of valine in valyl-RNA of TYMV is free was demonstrated by its capacity to be N-acetylated in the presence of acetic anhydride[6].

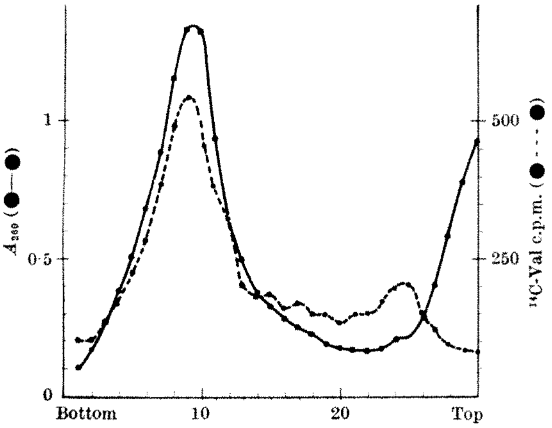

Fig. 2. Sedimentation pattern of ^{14}C-Val-RNA of TYMV. After incubation as described in Table 1, the charged RNA was isolated by the phenol procedure. It was layered over a 5–20 per cent sucrose gradient in 0·01 M sodium cacodylate (*p*H 6), and centrifuged in an 'SW 50' rotor for 3 h at 50,000 r.p.m. $A_{260\ \mathrm{nm}}$ readings were performed directly on the fractions collected; radioactivity was determined after cold TCA precipitation and filtration over 'Millipore'.

The half-life of valyl-RNA of TYMV was compared with that of valyl-tRNA of *E. coli* by incubation at *p*H 8·6: it was 60 min for both, which strongly suggests that in TYMV-RNA valine was esterified to the 2′ or 3′ position of the terminal nucleoside.

To determine the terminal nucleoside of TYMV-RNA which retained valine, we treated ^{14}C-Val-RNA by various nucleases and analysed the radioactive degradation products by thin-layer chromatography in different solvent systems (Fig. 3) and by paper electrophoresis; for comparison, ^{14}C-valyl-tRNA of *E. coli* was treated similarly. Both substrates yielded only valyl-adenosine or valyl-adenylate when treated by pancreatic ribonuclease or by snake venom phosphodiesterase, respectively. We conclude that valine is bound to the ribose moiety of adenosine on the 3′ end of the RNA.

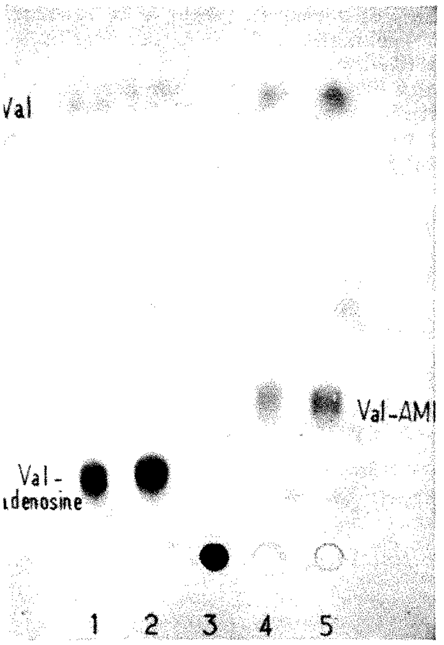

Fig. 3. Thin-layer chromatography of the radioactive products formed by nuclease digestion of ^{14}C-valyl-RNA of TYMV. ^{14}C-Valyl-RNA of TYMV was prepared as indicated in Table 1 and isolated by the phenol procedure; a sample of ^{14}C-valyl-tRNA of *E. coli* served as control. Each incubation mixture contained in 15 µl.; 50 pmoles of ^{14}C-valyl-RNA of TYMV (charged with 30 pmoles of ^{14}C-valine), or 600 pmoles of ^{14}C-valyl-tRNA of *E. coli* (charged with 30 pmoles of ^{14}C-valine), and either 2 µmoles of Tris-HCl (*p*H 7·4) and 5 µg of pancreatic ribonuclease, or 1 µmole of sodium-barbital–acetic acid (*p*H 8·6), and 25 µg of snake venom phosphodiesterase. After incubation for 20 min at 37° C, the samples were chromatographed on cellulose layer in a solvent containing ammonium sulphate (442 g/l.) : isopropanol (98 : 2) and autoradiographed. Treatments: (1) ^{14}C-valyl-RNA of TYMV plus pancreatic ribonuclease; (2) ^{14}C-valyl-tRNA plus pancreatic ribonuclease; (3) untreated ^{14}C-valyl-RNA of TYMV; (4) ^{14}C-valyl-RNA of TYMV plus snake venom phosphodiesterase; (5) ^{14}C-valyl-tRNA plus snake venom phosphodiesterase.

The identity of the bond joining valine to TYMV-RNA with that between valine and tRNA raises the question of the specificity of this viral RNA as acceptor of valine. The appearance of low molecular weight material (Fig. 2) suggests that valine could be bound to host tRNA trapped within the virus particle during the encapsidation process. This type of phenomenon is known to occur in the case of avian myeloblastosis virus[7,8]. In the case of TYMV-RNA, however, it seems improbable because a maximum of one valine molecule is bound per viral RNA, and no amino-acid other than valine is accepted. Moreover, when TYMV-RNA and ^{14}C-valyl-tRNA of Chinese cabbage were applied to the same sucrose density gradients, the analysis after centrifugation showed that valyl-tRNA had no detectable affinity for TYMV-RNA. A closer examination of the slowly sedimenting material of TYMV-RNA containing valine indicated that its sedimentation constant was somewhat higher than that of valyl-tRNA of Chinese cabbage, and must therefore originate from the degradation of TYMV-RNA during incubation. Although the possibility that a precursor of host $tRNA^{Val}$ might be strongly bound to TYMV-RNA cannot be excluded, the finding that 8 M urea does not dissociate them weakens this hypothesis.

Further results (unpublished) demonstrate certain similarities between $tRNA^{Val}$ and the TYMV polynucleotide moiety which accepts valine; this is shown by their interactions with three purified enzymes known to be specific for tRNA: tRNA. . .pCpCpA pyrophosphorylase, valyl-tRNA synthetase, and (after charging and acetylation) N-acyl-aminoacyl-tRNA hydrolase.

This work was supported by grants from the Centre National de la Recherche Scientifique, Départment de Biologie du Centre Nucléaire de Cronenbourg, 67-Strasbourg, the Délégation Générale à la Recherche Scientifique et Technique and the Commissariat à l'Energie Atomique (Saclay).

We thank Dr A. L. Haenni for her advice and help, Dr L. Hirth for supplying TYMV, Dr G. Ourisson for help in the preparation of the valyl-amide of Tris, and Dr G. Dirheimer for discussion.

Bone Marrow Transplantation in Irradiated Monkeys: Chromosome Aberrations in Donor Cells

SERIOUS chromosome injuries, of a type not previously reported, have been revealed unexpectedly in many donor cells during studies of bone marrow repopulation after transplantation to irradiated monkeys.

We studied baboons (*Papio hamadryas*) and rhesus monkeys (*Macaca mulatta*) exposed to ^{60}Co γ-irradiation in doses of 800 to 1,500 rads (dose rate, 50–200 rads/min). One and a half to two hours after irradiation, they received autologous or allogeneic bone marrow in doses of 2–5×10^8 viable nucleated cells per kg of body weight. In allotransplantation, females were used as donors and males as recipients. Because allogeneic bone marrow causes acute secondary disease in monkeys, with differentiation of haemopoietic cells only in a lymphoid direction and rapid "allergic death" of the immunocytes produced[1], this part of the experiment was done on monkeys thymectomized 6–12 weeks previously, in which the disease could not develop. The karyologic examination of bone marrow was made by the method of refs. 2 and 3.

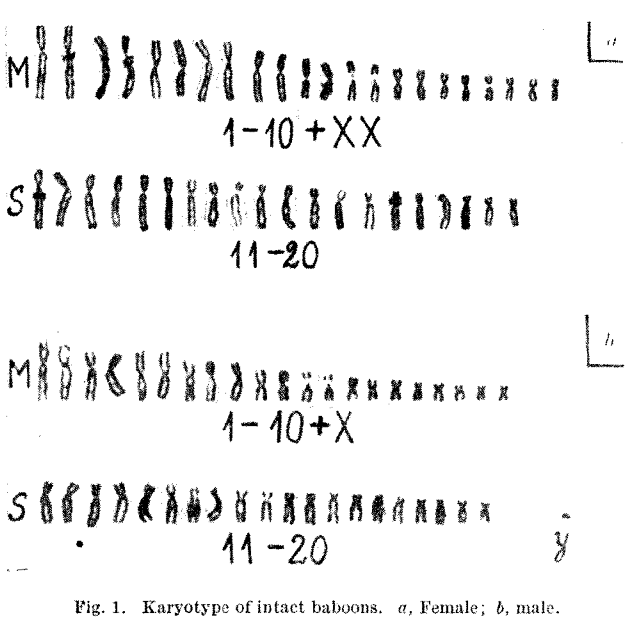

Fig. 1. Karyotype of intact baboons. *a*, Female; *b*, male.

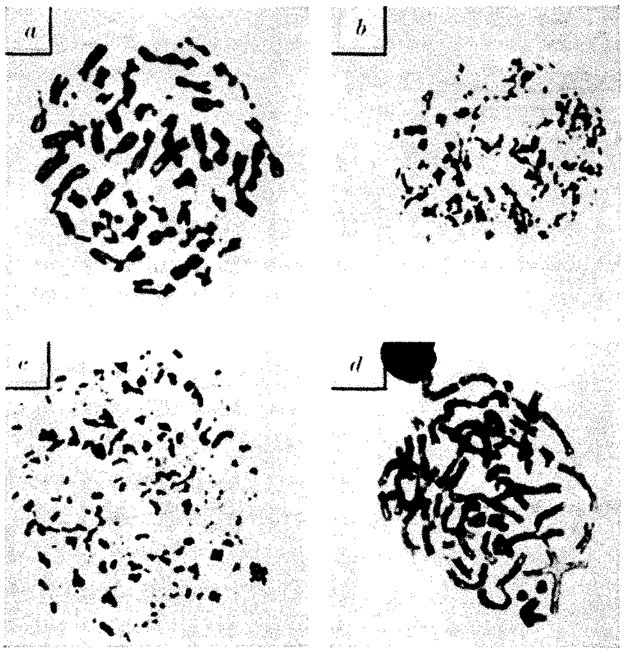

Fig. 2. Considerably injured cells from bone marrow of irradiated monkeys: *a*, numerous chromatid and isochromatid breaks (baboon; four days after exposure to 1,000 rads); *b*, *c*, pulverization (baboon; two days after exposure to 1,500 rads); *d*, breaks, chromatid translocations (baboon; four days after exposure to 1,500 rads).

The normal karyotype was studied on four baboons and two rhesus monkeys. The modal number of chromosomes in both species was 42. The cells of a male are easily distinguished from those of a female by the presence of a single acrocentric chromosome (*Y* chromosome) (Fig. 1). Aneuploid cells (about 5 per cent) were represented only by hypodiploids. In a series of 215 metaphases studied, gaps were found in three and a chromosome fragment in one. On the whole, the karyotype of the given monkey species was consistent with those described[4-6].

In the first 2–4 days after irradiation only considerably injured cells (Fig. 2) with numerous chromatid breaks and translocations were found in the monkeys; severe chromosome fragmentation (pulverization) was frequent. This was encountered in cells which had been exposed to the direct effect of ionizing radiation, for identical phenomena were revealed at the same time in control animals not given bone marrow. Active repopulation by the transplant occurred from the second week after irradiation (Table 1). Along with a few considerably injured cells a great number of uninjured metaphases belonging to the bone marrow donor (*XX*) were found, some of which had definite structural chromosomal abnormalities in the chromosomes. For analysis we accepted as identified only cells containing all forty-two chromosomes; those with even one chromosome lost or those with translocations were considered not identified. With such a strict approach all three monkeys were found to have chromosome aberrations in 7 to 30 per cent of cells of the bone marrow donor (Fig. 3*a*, *b*, *c*). Chromatid and isochromatid breaks were almost equal in frequency, whereas translocations were much rarer, as can be seen from Table 1.

Thus without taking into account the considerably injured cells which were apparently recipient cells fatally damaged by the direct effect of radiation, we found that 19 per cent of cells (63 of 327) carried structural chromo-

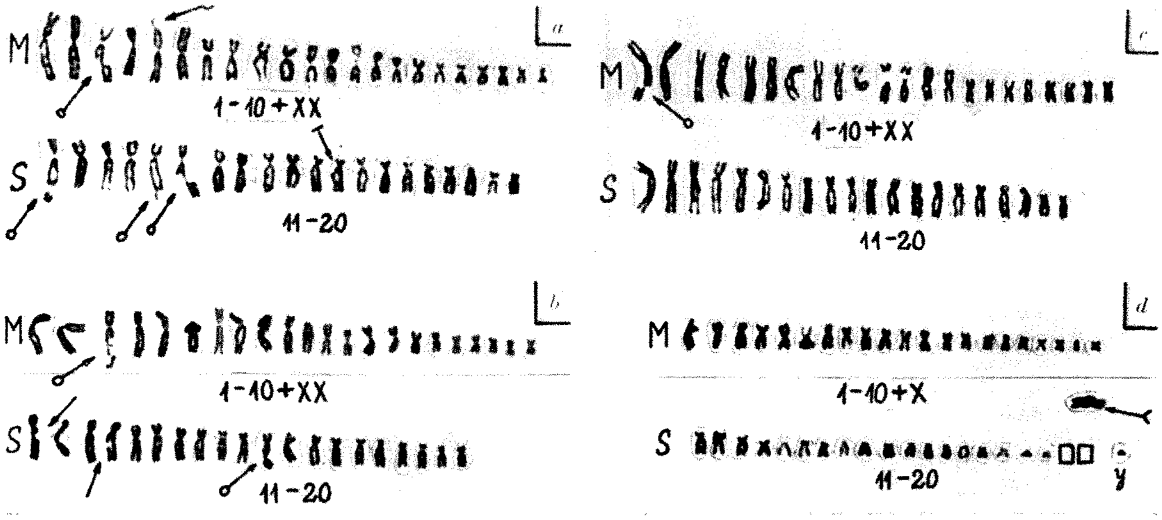

Fig. 3. Structural chromosomal abnormalities in haemopoietic cells of irradiated monkeys with transplanted bone marrow: *a*, baboon (*XY*) exposed to 1,000 rads and given bone marrow (*XX*) transplantation; eleven days after transplantation. Donor's cell: ○→, isochromatid break; |→, chromatid break. *b*, The same monkey fifteen days after transplantation. Donor's cell: ○→, isochromatid (chromosome) break; →, gap. *c*, Rhesus monkey (*XY*) exposed to 800 rads and given bone marrow (*XX*) transplantation; twelve days after transplantation. Donor's cell: ○→, isochromatid break. *d*, Baboon (*XY*) exposed to 900 rads and given transplantation of autologous bone marrow; 371 days after irradiation. >→, Triradial exchange figure; two chromosomes of group *S* are absent.

somal abnormalities; all identified aberrant cells (52 of 63) were donor's cells. An increase in the number of cells with gaps was also revealed among cells undergoing repopulation (12 of 327 compared with 3 of 215 in normal conditions); in some cases the gaps were numerous and much larger than those encountered in intact monkeys (Fig. 3*b*). By the end of the third postirradiation week the number of injured cells was reduced.

To exclude the influence of factors such as foreign antigenic surroundings, thymectomy of the recipient or possible allogenic inhibition, we conducted experiments with transplantation of autologous bone marrow (Table 2), and also revealed in such cases cells carrying similar chromosome aberrations. Because of the absence of markers we could not establish directly whether these cells belonged to the transplant. But with the irradiation dose used (1·5 to 2 LD_{99}) all cells which had been exposed to the direct effect of radiation and had started mitosis in the early postirradiation period carried serious chromosome injuries. It seems most probable that cells with relatively small injuries belonged to the transplant. This naturally does not refer to a monkey examined one and two years after irradiation. The two cells with chromatid translocations (Fig. 3*d*) found in it may have been the descendants of both irradiated and non-irradiated precursors. In these experiments, if greatly injured cells were not taken into account, in the first three weeks after transplantation 21 (14 per cent) of 148 cells carried chromatid and isochromatid breaks too and the number of cells with gaps (5 of 148) was also increased.

Two and a half months after irradiation the number of aberrant cells was reduced (1 of 35). Such a close resemblance between the relative numbers of aberrant cells following auto and allotransplantation suggests that in cases of autotransplantation these injuries are also carried by grafted cells.

The chromosome injuries encountered with both allo and autotransplantation were not self-reproducing and were lost at the first mitosis; no clones of injured cells were found. This suggests that the damage is incurred not only during transplantation or soon after it. Indeed, in some cases 15 to 20 per cent of all mitotic donor cells were aberrant 12 to 15 days after transplantation. Because the cellularity of the bone marrow was restored to a

great extent by that time (it reached 15,000 to 30,000 per mm^3 as compared with 200 to 1,000 per mm^3 six days after irradiation at the depth of aplasia), the total number of injured cells exceeded the total number of transplanted cells capable of prolonged proliferation.

From this it can be concluded that factors which can cause chromosome aberrations in the proliferating haemopoietic cells exist in the body during the first weeks after irradiation. There are no facts pointing to this type of activity in "radiotoxins". It seems possible that injuries to donor cells may be caused by a virus infection which develops frequently in monkeys suffering the severest form of acute radiation sickness. Whatever the mechanism of such injuries, however, the results should be taken into account in radiobiological studies. They suggest in particular that not every cell with chromosome aberrations found in an irradiated animal has been exposed to the direct action of radiation.

Evidence against a Presynaptic Action of Acetylcholine during Ganglionic Transmission

THE receptors for the neurotransmitter in sympathetic ganglia (acetylcholine) are usually thought to be located exclusively on the postsynaptic membrane. Koelle[1,2] has suggested, however, that the presynaptic nerve terminals are also sensitive to acetylcholine, and that, during normal transmission, the acetylcholine initially released by the preganglionic nerve impulse might depolarize the terminals and release a further quantity of acetylcholine, so amplifying the transmitter release process. Koelle recognized that this hypothesis was similar to that advanced in connexion with transmitter release from adrenergic fibres[3], and suggested that such "cholinergic links" may be a widespread feature of neurotransmitter and neurosecretory systems.

At present, however, experimental evidence for the presence of presynaptic acetylcholine receptors in ganglia is inconclusive. The principal evidence originally advanced was that the effect of carbachol (a stable analogue of acetylcholine) on the cat superior cervical ganglion was depressed following degeneration of the preganglionic nerves[4], from which it was concluded that the stimulant action of carbachol on normally innervated ganglia results principally from the liberation of acetylcholine from the preganglionic fibres. The force of this argument is diminished, however, by the failure of subsequent investigations to confirm denervation subsensitivity in ganglia (refs. 5, 6 and personal communication from R. L. Volle).

A more direct approach would be to find out if application of acetylcholine could release acetylcholine from the preganglionic fibres. Some experiments along these lines on the perfused cat superior cervical ganglion indicated that carbachol could release acetylcholine, but the mode of action of carbachol differed radically from that of preganglionic nerve stimulation: thus, unlike the response to nerve stimulation, the effect of carbachol was not prevented by omitting Ca^{2+} from the perfusion fluid, yet was reduced by curare alkaloids, hexamethonium and atropine[7,8]. In view of these differences, the relevance of the effect of carbachol to the postulated action of neurally released acetylcholine on the presynaptic terminals is questionable. For this reason further experiments of this nature—but using acetylcholine itself as the stimulant agent—seemed necessary, and have been undertaken in the present study.

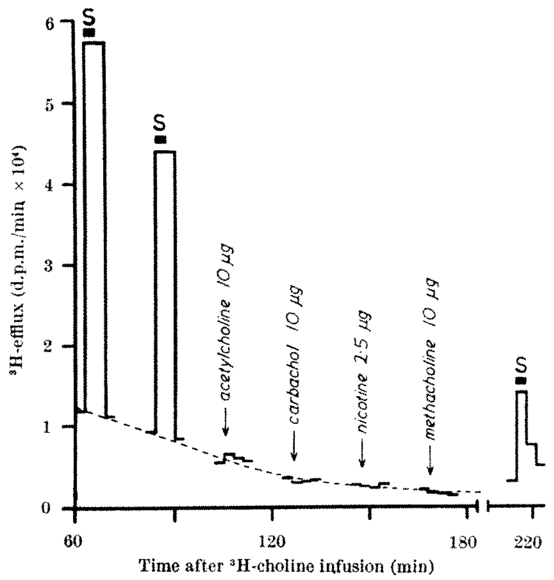

Fig. 1. Effects of preganglionic nerve stimulation (S = 3 min at 10 Hz) and injections of cholinomimetic agents (in 0·1 ml. Ringer–Locke) on the efflux of tritium from a perfused cat superior cervical ganglion. Efflux into unlabelled perfusion fluid was measured, the ganglionic acetylcholine having been previously labelled by perfusing with ^{3}H-choline solution while stimulating the preganglionic nerve trunk (see text). The discontinuities in the efflux curve were occasioned by the intermittent blood perfusion[11].

The chief difficulty presented by such experiments is that of detecting the small amounts of acetylcholine released from the nerves in the presence of much larger quantities injected: for this, conventional bioassay techniques are clearly unsuited. Instead, we have labelled the neural acetylcholine stores radioactively, by infusing radioactively labelled choline while stimulating the preganglionic nerve. Then some of the unlabelled acetylcholine originally present is released and replaced by labelled acetylcholine, formed from the labelled choline[9]. Release of neural acetylcholine may then subsequently be detected by radioassay.

The experimental procedure was as follows. Cats were anaesthetized with chloralose (70 mg/kg intravenously) after induction with halothane. The superior cervical ganglion was perfused with oxygenated Ringer–Locke solution containing physostigmine (10 μg/ml.), as described by Perry[10], but modified in that the cat's own blood was passed intermittently through the ganglionic circulation to reduce ganglionic oedema[11]. To label the neural acetylcholine stores, ^{3}H-choline (15 μCi, 1 μg/ml.; Radiochemical Centre) was added to the perfusion fluid and perfused through the ganglion for 15 min while stimulating the preganglionic nerve trunk at 10 to 50 Hz (0·5 ms duration, 10 V). The perfusion fluid was then changed to Ringer–Locke solution containing unlabelled choline for the remainder of the experiment, and total radioactivity in the effluent perfusate monitored by liquid scintillation counting. To separate ^{3}H-choline and ^{3}H-acetylcholine in the perfusate, samples of perfusate were freeze-dried, choline and acetylcholine were dissolved in ethanol, and the ethanol solution was subjected to paper electrophoresis[12]. Choline and acetylcholine bands were located by iodoplatinate spray, cut out, extracted into phosphor, decolorized with NH_4OH, and radioactivity was counted. A single run sufficed to remove 98–99 per cent of choline from acetylcholine. Throughout the experiment, ganglionic responses to preganglionic nerve stimulation, and to drug injections (administered into the influent perfusion stream in a volume of 0·1 ml. warmed Ringer–Locke), were monitored by recording the contraction of the nictitating membrane.

Stimulation of the preganglionic nerve trunk at 10 Hz while perfusing with unlabelled choline solution regularly increased the amount of tritium in the effluent perfusate (Fig. 1). Separate measurement of acetylcholine and choline in the perfusate showed that this increased radioactivity arose entirely from an increased level of ^{3}H-acetylcholine. The amounts of ^{3}H-acetylcholine released declined with successive periods of nerve stimulation, whereas the total acetylcholine released (measured by bioassay on the rat blood pressure) remained constant. This fall in ^{3}H-acetylcholine specific activity, which was an exponential function of the number of nerve impulses, was presumably the result of replacement of ^{3}H-acetylcholine released by unlabelled acetylcholine synthesized from the unlabelled choline in the perfusion fluid—that is, the reverse of the labelling procedure. By extrapolating the specific activity of the released ^{3}H-acetylcholine to zero impulses, a rough estimate of the original specific activity of the releasable ^{3}H-acetylcholine could be obtained: this was between 25 and 75 per cent of that of the ^{3}H-choline infused.

Acetylcholine was injected into the perfusion stream in nine experiments (seventeen injections), in doses from 5 to 100 μg in 0·1 ml. Ringer–Locke. These injections produced contractions of the nictitating membrane which were frequently as great as, and sometimes greater than, those elicited by preganglionic nerve stimulation. Nevertheless, acetylcholine injections did not release appreciable amounts of ^{3}H-acetylcholine. In most instances (Fig. 1) the total radioactivity in the effluent perfusate was hardly altered following such injections. When total radioactivity was increased (five injections), it was found to result, not from a selective increase in ^{3}H-acetylcholine, but from an increased efflux of ^{3}H-choline. In such cases, the acetylcholine injection greatly increased the perfusion flow rate through the ganglion, and also increased the efflux of extracellular marker substances (^{14}C-sucrose or $Na_2{}^{35}SO_4$). This suggests that the ^{3}H-choline was derived from extracellular rather than intraneuronal sources.

Carbachol, nicotine, tetramethylammonium and methacholine were no more effective than acetylcholine in releasing ^{3}H-acetylcholine. Like acetylcholine, carbachol and methacholine (both effective ganglionic vasodilators) sometimes increased ^{3}H-choline efflux. Because methacholine did not stimulate the ganglion, this effect was clearly unrelated to ganglion stimulation, as indeed the observations with acetylcholine suggest.

Injection of KCl augmented the release of ^{3}H-acetylcholine, but only in concentrations (120 mM) three times greater than that which produced a maximal postganglionic response. It seems that, even with this non-specific stimulant, the postganglionic response cannot be ascribed to any material extent to release of acetylcholine.

Full interpretation of these results depends to some extent on the homogeneity of the ganglionic acetylcholine stores. There is evidence that a small fraction of the preganglionic acetylcholine (about 15 per cent) is not normally available for release by the nerve impulse[10,13]. In addition to this "reserve" acetylcholine, when a ganglion is perfused with physostigmine solution (as in the present experiments), a further and larger pool of "surplus" acetylcholine is formed[13]. This also does not directly contribute to the transmitter released by the nerve impulse[13], though it probably exchanges slowly with the releasable fraction[14,15]. Thus, during the relatively short period of perfusion with ^{3}H-choline, it is possible that neither the reserve nor surplus stores were appreciably labelled. In this case, if the injections of acetylcholine had released acetylcholine from these pools, this might not have been detected by radioassay.

Release of unlabelled acetylcholine is, however, irrelevant to the question whether neurally released acetylcholine exerts a presynaptic action, for acetylcholine pools not labelled during preganglionic nerve stimulation clearly do not directly participate in the transmission process. Our significant finding is that injections of acetylcholine were unable to release ^{3}H-acetylcholine, that is, to release acetylcholine from the pool discharged by the nerve impulse. This is strong evidence that a presynaptic action of acetylcholine does not play any part in the transmission process. Of course, it might be argued that the concentration of neurally released acetylcholine available to the hypothetical presynaptic receptors is greater than that attainable by injection—perhaps through some "barrier" to extrinsic acetylcholine. Such arguments are difficult to counter, though the substantial postsynaptic effects of the injections make the barrier concept rather unlikely. It would seem more reasonable to conclude that the neurotransmitter at the ganglion acts exclusively on the postsynaptic membrane.

During the course of this study observations were briefly reported[16] which are in agreement with our findings.

This study was aided by grants from the governors of St Bartholomew's Hospital and the American Medical Association Education and Research Foundation.

Definitive Evidence for the Short Arm of the *Y* Chromosome associating with the *X* Chromosome during Meiosis in the Human Male

MEIOTIC studies on the human male during the past thirty years, notably those of Koller[1] and Ford and Hamerton[2], have shown that the *X* and *Y* chromosomes associate at meiotic prophase. Whether the chromosomes form a true chiasma or not has never been demonstrated convincingly. Because the position of the centromeres of the chromosomes cannot be identified with certainty in meiotic preparations, there has been much speculation as to whether it is the long or the short arms of the *Y* chromosome which associate with the *X*. Thus, Sasaki and Makino[3] suggested that the *X–Y* chromosome association involved the short arms of the *Y*, and Hultén *et al.*[4] suggested the long arms of the *Y*. The best cytological evidence has come from McIlree *et al.*[5] on a male with a dicentric *Y* chromosome involving a presumptive deletion of the short arms. At diakinesis the dicentric *Y* chromosome did not associate with the *X*, and Jacobs therefore suggested that in normal circumstances the *Y* chromosome might have associated with the *X* by its short arms[6]. From phenotype–karyotype correlations, Ferguson-Smith[7,8] deduced that part of the long arms of the *Y* chromosome was homologous with part of the short arms of the *X*, and that this region was involved in the *X–Y* association. From the appearance of the *X–Y* association at diakinesis in testicular biopsies from a population of normal males, we have tentatively concluded that the short arms of the *Y* chromosome are involved in associating with the *X* chromosome.

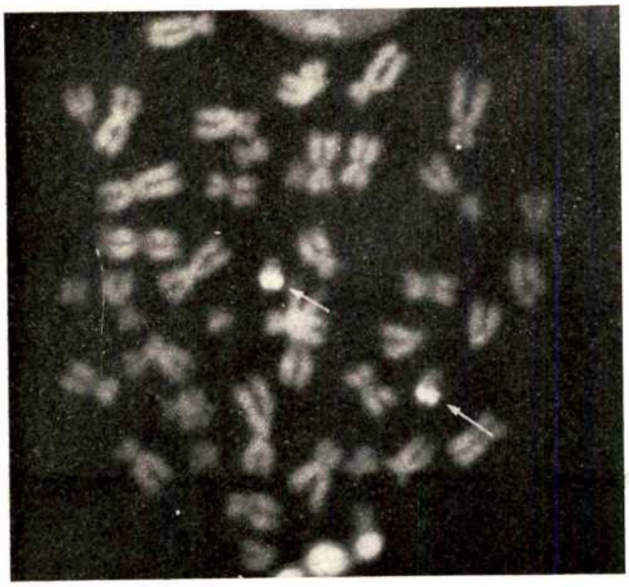

Fig. 1. Mitosis in a human male with *XYY* sex chromosomes showing a highly fluorescent distal region in the long arms of the *Y* chromosomes.

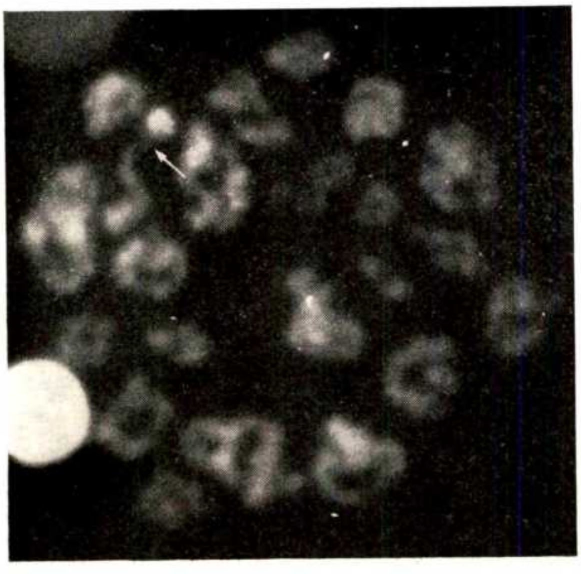

Fig. 2. **Diakinesis showing a highly fluorescent region at the extreme end of the *X–Y* bivalent in a normal male.**

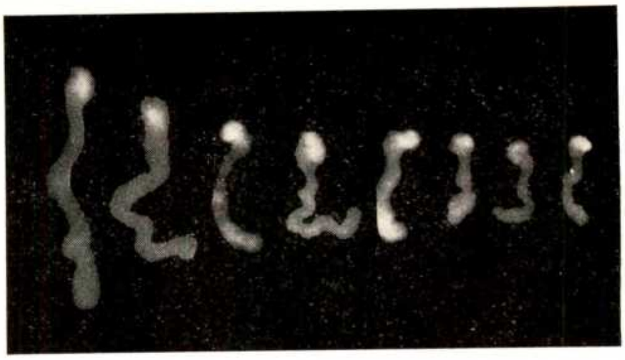

Fig. 3. Sex bivalents from different cells showing a fluorescent region at one end of each bivalent.

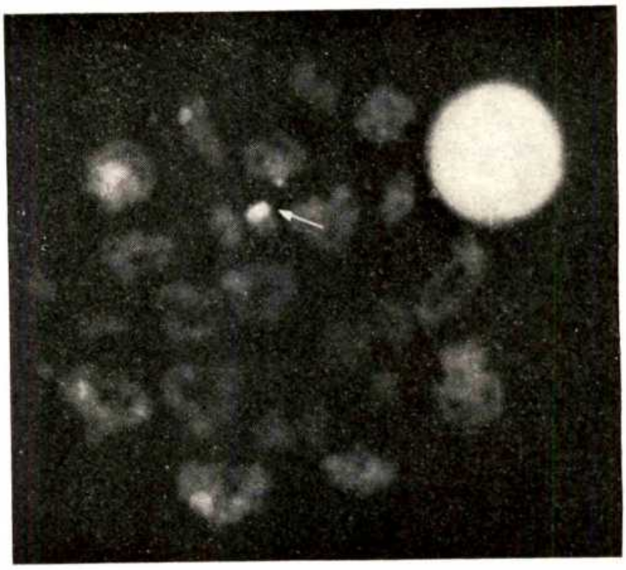

Fig. 4. Diakinesis showing a separate *Y* with a highly fluorescent and a low fluorescent region.

Zech[9] has demonstrated that the distal ends of the long arms of the human *Y* chromosome at mitosis fluoresce when stained with quinacrine mustard. The same effect can be achieved with quinacrine dihydrochloride[10] (Fig. 1) and the fluorescent *Y* chromatin can also be detected in interphase nuclei[11]. This can be used for determining the number of *Y* chromosomes present in the resting state nuclei of buccal mucosa cells. Moreover, the distal ends of the long arms of the *Y* chromosome fluoresce in meiotic cell preparations throughout all stages from spermatogonia through to mature spermatozoa[13]. We examined diakinetic cells prepared according to the technique of Evans *et al.*[12], stained them with quinacrine dihydrochloride[11] and viewed them with a Leitz microscope fitted with an HBO 200 light source and a 'Ploem' vertical illuminator. Fifty cells were selected from a normal male on the basis that they showed differential fluorescence and the *X–Y* bivalent was examined under ultraviolet light and under phase contrast. In all cases where the *X* and *Y* chromosomes were associated, the more highly fluorescent region was situated right at one end of the sex bivalent (Figs. 2 and 3) and not in an interstitial position. Where the *X* and *Y* chromosomes were lying free, the *Y* chromosome characteristically had a highly fluorescent area and a less fluorescent area (Fig. 4), thus mirroring the staining distribution in the *Y* chromosome during mitosis. It seems reasonable to suppose that the short arms, centromere and proximal parts of the long arm are situated in the less fluorescent part of the chromosome as they are in the mitotic *Y* chromosome.

We interpret these findings as definite evidence that it is the short arm of the Y chromosome which associates with the X during the first meiotic prophase.

The *Y* Chromosome in Human Spermatozoa

ATTEMPTS have been made to distinguish between spermatozoa of mammals containing either an X or a Y chromosome by looking for differences in size and surface properties of the two classes of cells (see refs. 1 and 2 for reviews), but the results of such approaches are equivocal. Another approach is to try to identify the X or Y chromosome within the head of the spermatozoon. Like Zech[3] and others[4,5], we have found that the distal end of the long arm of the Y chromosome in mitotic and meiotic metaphase nuclei of human cells displays a fluorescence more brilliant than that shown by the other chromosomes when stained with either quinacrine or quinacrine mustard. This property is carried by the Y chromosome into the chromatin of the mature spermatozoon.

Human spermatozoa were smeared on slides, dried in air, washed in absolute ethanol for 5 min and then stained for 20 min in 0·5 or 1 per cent quinacrine or 0·005 per cent quinacrine mustard dissolved in deionized water. The slides were thoroughly washed and the preparations mounted in water with a coverslip sealed down with varnish. The preparations remain in good condition for some hours. Spermatozoa were viewed with fluorescent illumination from a Zeiss photo-microscope using exciter filters with transmission ranges between 330 and 500 nm.

Chromatin in the heads of spermatozoa fluoresces with a yellow-green colour. The basal third of the head shows a denser fluorescent mass than the remaining upper portion and there is a sharp boundary between the two regions. Some sperm show a fluorescent body (F-body) that is much brighter than the bulk of the fluorescent material (Fig. 1). This F-body we believe to be the chromatin in the distal segment of the long arm of the Y chromosome. Spermatozoa stained with 0·05–0·5 per cent acridine orange, thought to intercalate into the DNA helix in the same way as quinacrine[6], display no F-bodies. Neither does ethidium bromide—a fluorochrome that shows the reverse pattern to quinacrine fluorescence with some types of heterochromatin[7]—differentiate the Y chromosome from other chromosomes in mitotic or sperm nuclei. The frequency of the F-body in spermatozoa of similar morphology was estimated (Table 1). Nearly half the quinacrine mustard-stained spermatozoa had an F-body, but it is seen less frequently after quinacrine staining. The lower frequency is probably caused by fading of the fluorescence with prolonged viewing, making detection of the F-body difficult. Fluorescence from quinacrine mustard fades much less. If the F-body is indeed chromatin of the Y chromosome it might be expected to be present in 50 per cent of the spermatozoa. The ratio may be lowered by the difficulty of resolving the F-body when it lies within the dense chromatin at the base of the head. Occasionally a spermatozoon was seen with two F-bodies; these spermatozoa had two tails and so may be diploid.

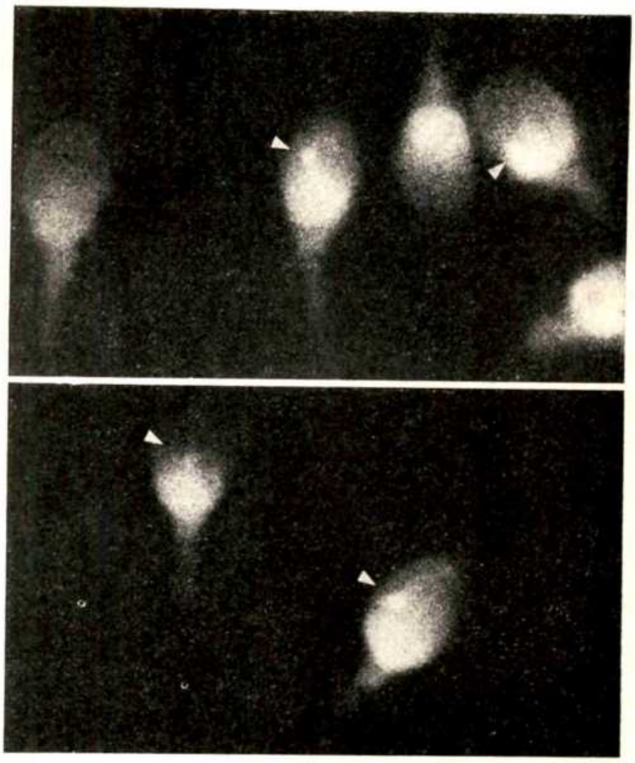

Fig. 1. A group of quinacrine-stained spermatozoa showing fluorescence. Some have a brightly fluorescent F-body (arrowed); others lack the F-body. × 4,300.

Table 1. FREQUENCY (PERCENTAGE) OF SPERM IN WHICH AN F-BODY IS VISIBLE (+) OR INVISIBLE (−)

Fluorochrome	Sample	+	−	No. of observations
Quinacrine mustard	1	46·5	53·5	200
	2	44·4	55·6	367
	1+2	45·1	54·9	567
Quinacrine	1	38·5	61·5	109
	2	40·6	59·4	404
	1+2	40·2	59·8	513

In more than 60 per cent of the spermatozoa with an F-body this was seen to lie at the boundary between the dense and less dense regions of chromatin (Fig. 1). In the others the F-body lay with equal frequency in either the dense or less dense regions. In some spermatozoa the F-body could be seen to lie against the membrane of the head.

We believe that the F-body represents the Y chromosome for the following reasons. In mitotic and meiotic metaphases part of the Y chromosome fluoresces more than any other chromosome; in interphase nuclei of normal XY males there is only one strongly fluorescent spot of chromatin, while in nuclei from XYY males there are two spots; nuclei of normal XX females exhibit no such spots[4]. In spermatozoa the frequency with which F-bodies are seen approaches that expected from the segregation of the Y chromosome at meiosis. We presume that spermatozoa lacking an F-body lack a Y chromosome and therefore may be X-bearing sperm.

The regular positioning of the F-body in the sperm head is of interest, for other authors have found an ordered arrangement of chromosomes in sperm[8–10]. There is, however, nothing which yet suggests structural differentiation of the Y chromosome within the sperm head when sperm chromatin is examined with the electron microscope[11–14].

Membrane Noise produced by Acetylcholine

ELECTROPHYSIOLOGICAL studies of the motor end-plate have shown that there is intermittent release of multimolecular ("quantal") packets of acetylcholine (ACh) from the nerve terminals, resulting in the appearance of discrete miniature end-plate potentials (m.e.p.p.). The number of molecular reactions which summate to make up a single m.e.p.p. is not known; it must be very large, for—with minimal doses of applied ACh—the membrane response seems to be continuously graded, even at amplitudes which are one or two orders of magnitude below that of the m.e.p.p. (see, for example, ref. 1, page 10).

It seemed possible, however, that during steady application of ACh to a motor end-plate the statistical effects of molecular bombardment might be discernible as an increase in membrane noise, superimposed on the maintained average depolarization. Suppose, for instance, that a maintained ACh potential V is made up of a statistical fusion of many "elementary" effects, each of instantaneous amplitude a and exponential decay with membrane time constant τ. Whether the elementary event arises from the reaction of one or more ACh molecules, with one or several receptor molecules, is left open. The average rate of such elementary effects necessary to maintain the depolarization V is then given by $n = V/a\tau$. For example, if $a = 0{\cdot}1\ \mu V$ and $\tau = 10$ ms, then to produce a 10 mV depolarization requires an average frequency of 10^7 elementary events per second. Applying Rice's theory of random noise[2] to this case, it can be shown that the expected ACh-induced voltage fluctuations across the membrane would have a root mean square value E of approximately $\sqrt{Va/2}$, which, for the example quoted, is about 22 µV. Conversely, knowing V and E, the elementary voltage amplitude a can be derived.

Fig. 1 shows that ACh-induced membrane noise can, in fact, be detected. We have used either bath application of ACh or, more conveniently, local application to a single end-plate by allowing ACh to diffuse from a micropipette (placed at sufficient distance to render ineffective any possible fluctuations in position or resistance of the pipette). Membrane potential changes during ACh application were recorded simultaneously on a low gain d.c. and a high gain a.c. coupled channel (time constant approx. 0·1 s). In the experiment illustrated in Fig. 1, a maintained depolarization of 8·5 mV was accompanied by membrane noise of 29·2 µV (root mean square value). The calculated value of a is 0·2 µV. Making an approximate allowance for non-linear summation of ACh potentials[3], the corrected values of V, E and a are 9·7 mV,

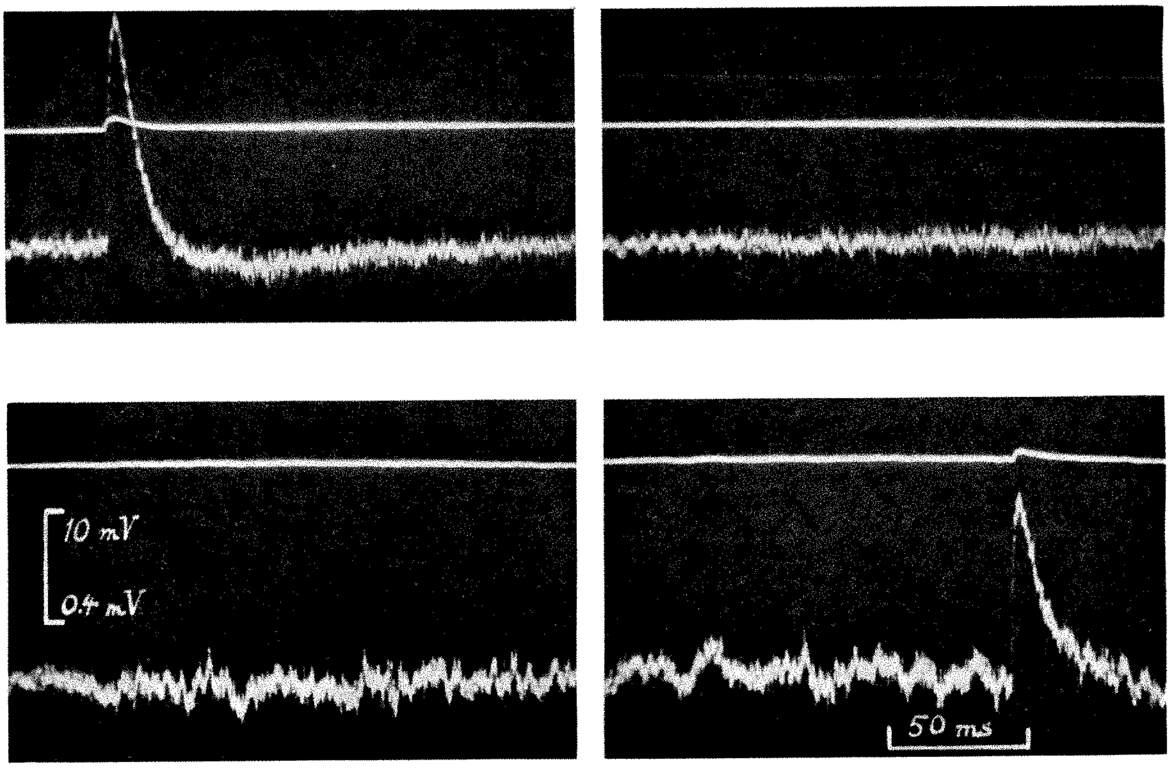

Fig. 1. Intracellular recording of membrane potential from end-plate region of frog muscle fibre. In each block, the upper trace was recorded on a low gain d.c. channel (10 mV scale); the lower was simultaneously recorded on a high gain a.c. coupled channel (0·4 mV scale). The records in the upper row are controls (no ACh); the lower row shows membrane noise during ACh application, by diffusion from a micropipette. In the lower records, the increased distance between a.c. and d.c. traces shows upward displacement of the d.c. trace because of ACh-induced depolarization. Two spontaneous m.e.p.p.s are also seen.

37·8 μV and 0·29 μV respectively. The average m.e.p.p. in this fibre (in presence of neostigmine) was 0·7 mV. Several experiments of this kind have been performed showing that the average amplitude of the m.e.p.p. is a few thousand times greater than the "elementary" ACh effect. It should be noted that the membrane noise described here accompanies ACh-induced depolarizations, but that no comparable effect was found during an electrotonic potential change of similar size, produced by passing direct current across the fibre membrane. We suggest that the membrane noise observed in these experiments arises from statistical variation of high-frequency collisions between ACh molecules and end-plate receptors.

Hypothalamic β-Adrenergic "Satiety" System antagonizes an α-Adrenergic "Hunger" System in the Rat

THIS communication proposes and tests the hypothesis that in the central nervous system, specifically in the hypothalamus, α and β-receptors function antagonistically in an adrenergic system, to regulate hunger in the rat. More specifically, this antagonistic relationship takes place between a hypothalamic α-adrenergic "hunger" system, which elicits eating behaviour, and a hypothalamic β-adrenergic "satiety" system, which suppresses eating behaviour. Before this research, there has been no evidence for a central β-adrenergic system functioning antagonistically with respect to a central α-adrenergic system.

Peripheral injections of three adrenergic agonists, norepinephrine, epinephrine or isoproterenol, have been shown to suppress food intake (refs. 1 and 2 and unpublished work of W. Goldman and D. Lehr). These anorexic effects, at least when induced by epinephrine and isoproterenol, have been partially blocked by a peripherally injected β-adrenergic antagonist (ref. 2 and unpublished work of W. Goldman and D. Lehr). On the other hand, in the central nervous system, studies using the technique of cannula-guided chemical stimulation of the brain, have shown that hypothalamic injections of norepinephrine or epinephrine increase food intake in satiated rats (refs. 3 and 4 and unpublished work of S. F. Leibowitz). Moreover, these eating effects were blocked by a centrally injected α-adrenergic antagonist (ref. 4 and unpublished results of S. F. Leibowitz). These results from peripheral and central studies formed the experimental background for our research on the brain. The main objectives of this research were to demonstrate the existence of a central β-adrenergic system, to confirm the existence of a central α-adrenergic "hunger" system, and, most significantly, to show that the antagonistic interaction between a central α and β-adrenergic system is a key mechanism in the regulation of hunger/satiety in the rat.

To investigate these hypotheses, we made the following predictions, and tested them in the hypothalamus. (1) If the eating response is mediated by hypothalamic α-adrenergic receptors, it should be elicited by a hypothalamically injected α-adrenergic agonist. (2) If the anorexic response is mediated by hypothalamic β-adrenergic receptors, it should be elicited by a hypothalamically injected β-adrenergic agonist. (3) This β-mediated anorexic response evoked by a β-adrenergic agonist should be blocked by a β-adrenergic antagonist but not by an α-adrenergic antagonist. (4) When an adrenergic agonist with both α and β-receptor activity evokes as its dominant response the β-mediated anorexic response, and when this particular agonist is combined with a β-adrenergic antagonist, the latent α-mediated eating effects of this agonist, previously masked by the dominant β-mediated anorexic effects, should now become apparent. (5) The β-mediated anorexic response evoked by an adrenergic agonist should be potentiated by an α-adrenergic antagonist. Evidence for the last two predictions would demonstrate most clearly the antagonistic interaction between central α and β-receptor control of eating behaviour.

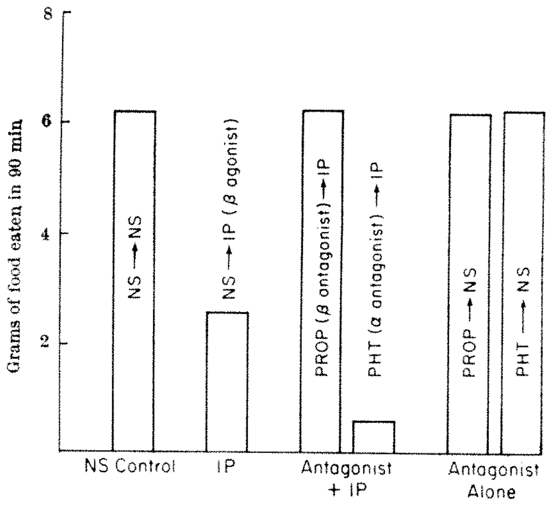

Fig. 1. Effects of hypothalamic injection of the β-adrenergic agonist, isoproterenol (IP), and of adrenergic antagonists upon food intake in food-deprived rats. The β-adrenergic antagonist is propranolol (PROP), the α-adrenergic antagonist is phentolamine (PHT), and the control medium is normal saline (NS). All drugs were injected directly into the hypothalamus. The score is mean grams eaten during the first 90 min after injection. The following meaningful comparisons were statistically reliable, at $P < 0\cdot001$: bars 1 : 2, 1 : 4, 2 : 3, 2 : 4, 3 : 4, 4 : 6.

A total of twenty-five male albino Sprague–Dawley rats (320 g) were stereotaxically implanted with unilateral chronic cannulas under 'Nembutal' anaesthesia, using the procedure described by Slangen and Miller[4]. All placements were aimed at the perifornical region of the hypothalamus immediately posterior to the anterior hypothalamus.

The following drugs were used: (–)-Norepinephrine bitartrate, an α-agonist (0·02 μmoles), (–)-isoproterenol bitartrate, a β-agonist (0·15 μmoles), (–)-epinephrine bitartrate, a β and α-agonist (0·10 μmoles), propranolol hydrochloride, a β-antagonist (0·14 μmoles), and phentolamine hydrochloride, an α-antagonist (0·07 μmoles). All drugs, except phentolamine, were dissolved in normal saline. Phentolamine was dissolved in distilled water. All drugs were injected directly into the hypothalamus through the same cannula, and the volume of each injection was always 1 μl.

All rats were fed and tested on Purina lab chow pellets. The first test consisted of injecting these rats, while food and water-satiated, with norepinephrine. During the first 30 min after injection, their food intake was significantly ($P < 0\cdot001$) increased from 0·2 g after saline to 2·7 g after norepinephrine. This eating response evoked by a centrally injected α-agonist agrees with the results of previous investigations[3,4] and confirms our first prediction.

All subsequent tests were carried out on the rats when they had been deprived of food for 18 h. The test, given every 3 to 4 days, consisted of measuring the rats' food intake during the first 90 min after drug injection. The rats were divided into two groups, one to be tested with

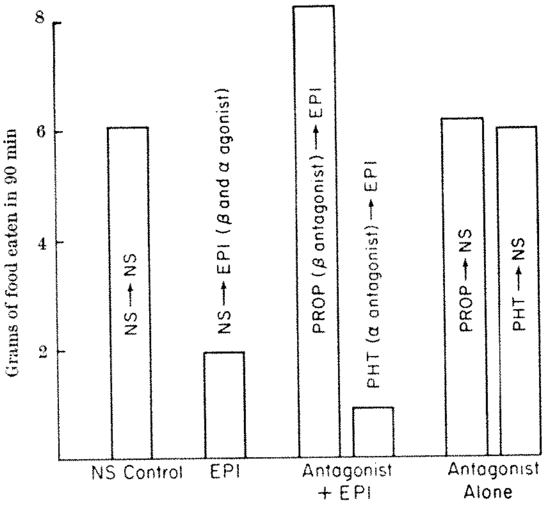

Fig. 2. Effects of hypthalamic injection of the β and α-adrenergic agonist, epinephrine (EPI), and of adrenergic antagonists upon food intake in food-deprived rats. The β-adrenergic antagonist is propranolol (PROP), the α-adrenergic antagonist is phentolamine (PHT), and the control medium is normal saline (NS). All drugs were injected directly into the hypothalamus. The score is mean grams eaten during the first 90 min after injection. The following meaningful comparisons were statistically reliable, at $P < 0{\cdot}001$: bars 1 : 2, 1 : 3, 1 : 4, 2 : 3, 2 : 4, 3 : 4, 3 : 5, 4 : 6.

isoproterenol, the potent β-agonist, and one with epinephrine, the potent β and α-agonist. Each rat in the two groups received six pairs of drug treatments, according to a Latin square sequence. The two injections of each pair were separated by 5 min. The six paired treatments for the two groups, which had either isoproterenol or epinephrine as their agonist, were: saline→saline, saline→agonist, propranolol→agonist, phentolamine→agonist, propranolol→saline, and phentolamine→saline.

The results of these experiments (Figs. 1 and 2) confirm all the predictions generated by the hypothesis that the regulation of hunger in the rat is mediated by hypothalamic α and β-adrenergic systems and that the receptors of the α-system elicit eating behaviour and the receptors of the β-system suppress eating behaviour. Unilateral hypothalamic injection of isoproterenol and epinephrine, two potent β-agonists, had a strong and almost immediate anorexic effect, which confirms our second prediction. These two drugs reliably suppressed food intake by 60 per cent and 70 per cent, respectively. These results, illustrated in the first two bars in Figs. 1 and 2, contrast clearly with the eating response elicited in satiated rats by hypothalamic injection of norepinephrine (the first prediction), and they provide strong evidence for the existence of hypothalamic β-adrenergic "satiety" receptors.

The third and fourth bars in Figs. 1 and 2 show the pronounced effects which the two centrally injected adrenergic antagonists have on anorexia elicited by hypothalamic β-adrenergic stimulation. These results confirm the third, fourth and fifth predictions in every respect. Propranolol, the β-antagonist, but not phentolamine, the α-antagonist, completely blocked the anorexia elicited by isoproterenol and epinephrine (third prediction), a finding which clearly demonstrates that such drug-induced anorexia is mediated by central β-adrenergic receptors. In the epinephrine-injected rats, propranolol induced a significant reversal of the effect of epinephrine on hunger, converting its anorexic effect into a strong hunger-stimulating effect (the fourth prediction). This epinephrine "reversal", which reveals the antagonistic relationship between hypothalamic α and β-receptors, caused these already hungry rats to eat 35 per cent more than they did when injected just with normal saline, or with propranolol and normal saline (bars 1, 3 and 5 in Fig. 2). The anorexic effect of isoproterenol, although completely blocked by propranolol, was not reversed in the direction of hunger-stimulation, presumably because its α-receptor activity is too weak to elicit an enhanced eating response (bars 1 and 3 in Fig. 1). Hypothalamic pretreatment with phentolamine, the α-antagonist, reliably potentiated both isoproterenol and epinephrine-induced anorexia, which confirms the last prediction (bars 2 and 4 in Figs. 1 and 2).

Neither the α nor the β-antagonists had any effect of their own on food intake at the relatively low doses used in this experiment (bars 5 and 6 in Figs. 1 and 2). Preliminary results from this laboratory, however, show that, at somewhat higher doses, phentolamine and propranolol suppress and enhance food intake, respectively. These findings lend further support to the hypothesis that the physiologically active central hunger-regulating mechanism in the rat consists, at least in part, of two adrenergic systems, α and β, which interact antagonistically.

Finally, the concepts and techniques presented in this study were used to investigate the well known amphetamine-induced anorexic effect, which is not expected on the basis of the norepinephrine-releasing properties of this drug. These investigations have yielded very interesting data which strongly suggest that the suppressing effect of amphetamine on food intake is mediated by hypothalamic β-adrenergic "satiety" receptors.

These findings confirm the hypothesis that hunger in the rat is regulated by a hypothalamic α and β-adrenergic mechanism. These central α and β-receptors interact in an antagonistic manner, with the α "hunger" receptors eliciting eating behaviour and the β "satiety" receptors suppressing eating behaviour. These results demonstrate that hunger and satiation can now be neurochemically differentiated in the hypothalamus of the rat.

I thank Miss Sandra Schnall and Mrs Lilian Rochlitz Quintão for technical assistance, Miss Elizabeth Sherwood for implanting the cannulas, and Dr N. E. Miller for a critical reading of the manuscript. I also thank Ayerst Laboratories, Sterling-Winthrop Research Institute and Ciba Pharmaceuticals for supplies of the drugs. This work was supported by grants to Dr N. E. Miller from the National Institute of Mental Health and from Hoffmann–La Roche.

Integration and Analysis of Movement Information by the Visual System of Flies

INTERNEURONES capable of discriminating motion have been found in the medulla, lobula and central brain of such insects as *Calliphora phaenicia* and *Musca domestica*[1-3]. These interneurones discharge selectively in response to simple motion in one direction. I report here the demonstration of units that respond to complex motion.

Unitary discharges were recorded from the medulla, lobula and other brain regions of *Boettcherisca peregrina* through glass microelectrodes with tips less than 0·3 μm in diameter. Stimuli were given by moving a light spot, 2 mm in diameter, projected on to a white screen 10 cm in front of the fly. The light from a microscope lamp with source intensity 5 V was conducted to the screen by a light guide 2 mm in diameter and 1 m in length.

Almost all units which respond to a moving spot were found also to discharge in response to steady illumination within their receptive fields, but the discharge frequency was not as great as in the response to the moving spot. Two examples of units that responded to complicated motion are shown in Figs. 1 and 2. The unit illustrated in Fig. 1 responded to motions in the left half of the visual field, the centre of which was on a line extended from the axis of the head, as described by Bishop *et al.*[2]. The only motions which elicited spikes were: downwards in the left half of the visual field, from right to left in the upper left quadrant, and from left to right in the lower left quadrant. In other words, this unit discharged when the spot was moved counterclockwise in the left half of the visual field. The other unit (Fig. 2) responded when the spot was moved counterclockwise in the complete visual field. Several examples are shown in Fig. 3. Neurones with the response pattern illustrated on the right in *A* discharged in response to motions in all directions. Units shown on the left in *A* responded mainly to motions of two directions, upward and left to right, but also discharged with lower spike frequency in response to motions in the opposite directions. These two kinds of neurone were found in the optic medulla region. The visual field was relatively wide (visual angle of about 180°) for these units. Neurones which could discriminate complicated motion, such as are illustrated in *B*, were found in the optic lobula region. The size of the visual field for these units was relatively moderate (visual angle of about 90°) or narrow (30°–40°). The visual field of the unit shown in the middle of *B* was limited to the upper half only. The motion pattern illustrated in *C* was extremely analytical and also integrative. This unit responded to motion in two directions, upward and right to left, in the narrow central area of the visual field (visual angle of about 30°), while it discharged in response to motions in the opposite directions, downward and left to right, in the area surrounding the central visual field. This unit was found in the corpora ventralia of the brain. I also found the following units: a unit that inhibited the spike discharges corresponding to a fixed spot, or the spontaneous ones, when the spot moved in one direction; an "alerting" unit that discharged only when the spot started to move and did not elicit spikes if successively stimulated in the same way; and a unit that responded to clockwise movements of the spot.

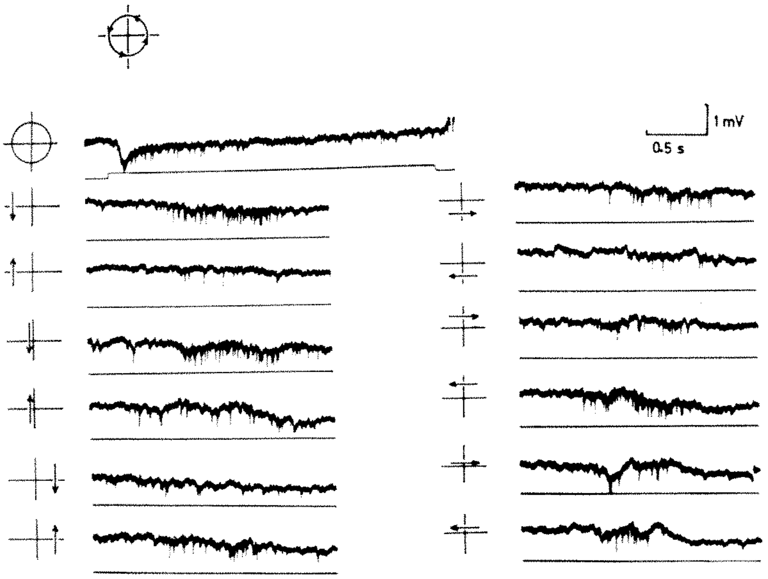

Fig. 2. Responses of a directionally selective unit to a moving spot. This unit discharged when the spot moved counterclockwise around the centre of the visual field (see inset), regardless of the distance from the centre.

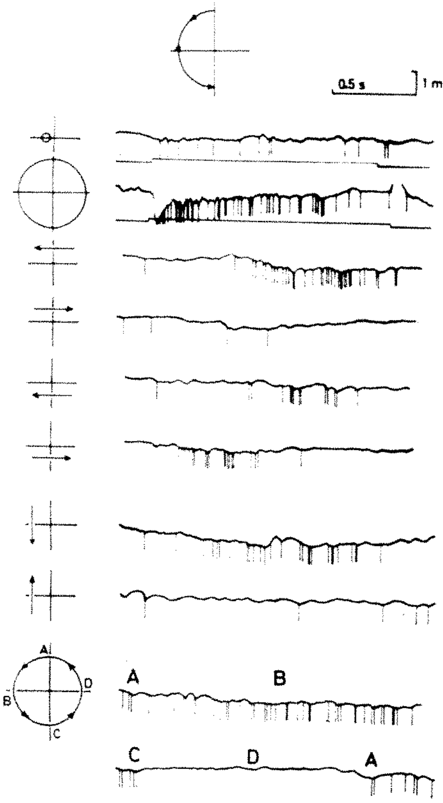

Fig. 1. Responses of a directionally selective unit to a moving spot. The geometrical centre of the visual field, which is on a line extended from the axis of the head, is indicated by a cross. Arrows show the direction of movement of the spot. As shown in cases where the spot moves horizontally, discharges are scarcely elicited at all when the spot moves through the right half of the visual field. In other words, this unit discharges when the spot moves counterclockwise in the left half of the visual field, as indicated in the bottom (*A* to *C*) and top inset. Discharges were also elicited by steady illumination in one spot (top record) or in all visual fields (second record).

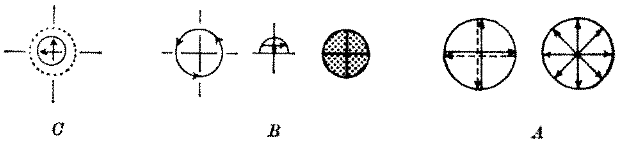

Fig. 3. Examples of the patterns of motion discrimination. Units found in the peripheral region (optic medulla) responded non-selectively to motions in various directions (right of *A*), or were merely capable of gross discrimination of motion (left of *A*). Arrows with a broken line indicate that the discharge frequency in response to the movement of the spot in the direction shown is less than that denoted by arrows with the solid line. In the lobula region (*B*), the motion pattern is more complicated or integrative than in the medulla region. The shaded circle indicates inhibition of discharges by illumination (right of *B*). The unit denoted in the middle of *B* responded to motions in two directions in only the upper half of the visual field. The unit shown in *C* was found in the corpora ventralia of the brain. It responded to movement of the spot in two directions within the narrow central visual field and to motions in the opposite directions in the surrounding visual field (indicated by dotted circle).

In general, the following tendencies seem to be present: with transmission of the visual information from the peripheral neurones to the central structure, (1) the direction of motion responded to is restricted, (2) the discrimination of motion becomes strict, as shown by the reduction or elimination of spikes in response to motions in the opposite direction, and (3) directions of motion are combined in a complex way. Further, in a few neurones of the central brain the discrimination of motion becomes so strict that (4) the direction of the motion which elicited spikes was opposite for the central and surrounding visual fields, and (5) the discriminable speed of movement of the spot was limited. These findings seem to provide interesting data about the perception of moving objects and its biological meaning, especially with respect to the perception of circulatory motion: for example, in relation to the sense of equilibrium when the body rotates in flight.

Determination of a Behavioural Transfer Function by Frequency Analysis

TRANSFER functions are used by engineers as a means of describing, in a single equation, the relationship between the input and output of a system. Frequency analysis is a classic method of determining transfer functions in physical systems, and has also been used for quasi-behavioural systems, such as those controlling optokinetic responses[1] and the pupillary light reflex[2]. In the behavioural context, a transfer function describes the stimulus–response relationship in all possible stimulus conditions. It also makes it possible to compare biological and physical systems directly. In other words, it offers an explanation of behaviour that is independent of the "hardware" involved. In this preliminary report, frequency analysis is applied to behaviour, with the eventual aim of accounting for motivational phenomena rigorously and quantitatively.

The water intake of many species is positively correlated with ambient temperature, and in some species temperature-induced water loss may be responsible for increased drinking[3]. The evidence, however, suggests that pigeons drink in direct response to ambient temperature changes, in the absence of dehydration (refs. 4, 5 and our unpublished results). Our study deals with the determination of a transfer function relating thirst motivated behaviour to ambient temperature.

Three Barbary doves (*Streptopelia risoria*) were trained to obtain 0·1 cm³ water rewards by pecking at an illuminated key in a Skinner box, which was installed inside a climatic cabinet. Rewards were delivered on a random interval schedule, with a mean interval of 2 min (VI 2 min). The animals were trained for ten weeks, until they responded at a constant rate for a 3 h period after 48 h without water.

The animals were tested every two days, and were water deprived during the intervening periods. Tests were conducted alternately at a constant temperature of 15° C and at a temperature fluctuating sinusoidally between 5° C and 25° C. Tests were run at frequencies of 0·40, 0·50, 0·66, 1·00, 1·33, 2·00 and 4·00 cycles/h. The accuracy of the sinusoidal temperature function was ±0·25° C. Pecks delivered and rewards obtained were recorded on an event recorder throughout the whole of each 3 h test period, but the records for the first and last 30 min were discarded to avoid possible effects of initial transients and satiation respectively.

The results showed that the mean response rate was the same at all frequencies and distribution of rewards was not changed as the response rate fluctuated. The results of two sample test sessions at different frequencies are shown in Fig. 1. Preliminary examination of the results indicated that the frequency response was similar to that of a first-order system. On this basis, the appropriate transfer function is given by

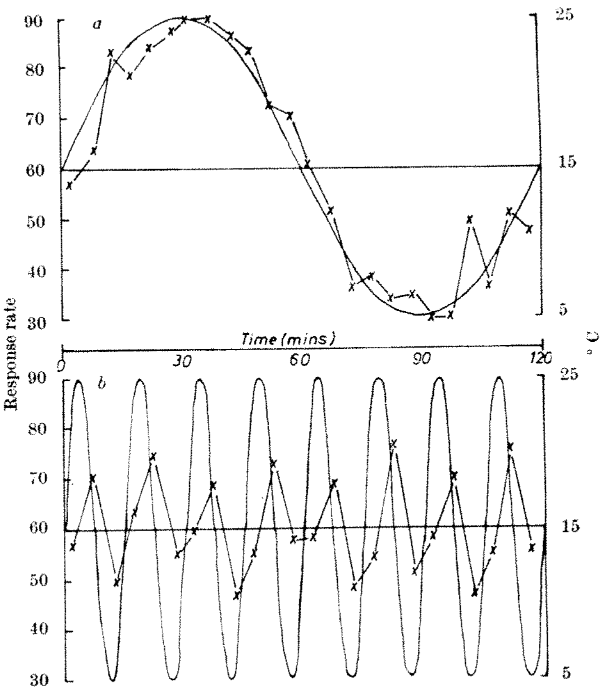

Fig. 1. Sample results at temperature frequencies of (*a*) 0·5 cycles/h and (*b*) 4 cycles/h. Response rate in pecks/5 min is indicated by crosses, ambient temperature by the continuous curve.

$$H(i\omega)=\frac{k}{i\omega T+1}$$

where k is the gain and T the time-constant of the system. The phase angle between input and output is given by

$$\varphi=-\text{arc tan }\omega T\triangleq\angle H(i\omega)$$

The results provide a series of values of φ for corresponding values of ω. For example, at a frequency of 1 cycle/h the observed phase-lag is 31·2°.

$$\varphi=-\text{arc tan }\omega T=-\text{arc tan }2\pi T=-31{\cdot}2$$

From this equation, $T=0{\cdot}6056/2\pi T$ h$=5{\cdot}78$ min. On average, the value of T was found to be equal to 5·57 min, and this value forms the basis of the phase plot illustrated in Fig. 2*a*.

The expected values of the amplitude ratio AR as a function of frequency can now be calculated.

$$AR=|H(i\omega)|=\frac{k}{(1+(\omega T)^2)^{\frac{1}{2}}}$$

$$\log AR=\log_{10}k-\text{c}\tfrac{1}{2}(\log_{10}(1+(\omega T)^2))$$

An AR value of 1 can be defined when two conditions are satisfied: (1) that the average response rate is the same at the lowest observed frequency as at infinite frequency; and (2) that the same empirical response amplitude is found at two different low frequencies. The ratio between these and the temperature amplitude is then arbitrarily defined as unity. In practice, both these conditions were satisfied, and the procedure was used to construct the predicted curve in Fig. 2*b*, namely

$$\log_{10}AR=-\tfrac{1}{2}(\log_{10}(1+(\omega T)^2))$$

Comparison with the observed AR, calculated on the same basis, indicates good correspondence with the expected values (Fig. 2*b*), and to this extent the hypothesis of a first-order system is confirmed.

The results indicate that appetitive drinking behaviour can occur as a rapid response to changing ambient temperature. The time-constant of the response, 5·57

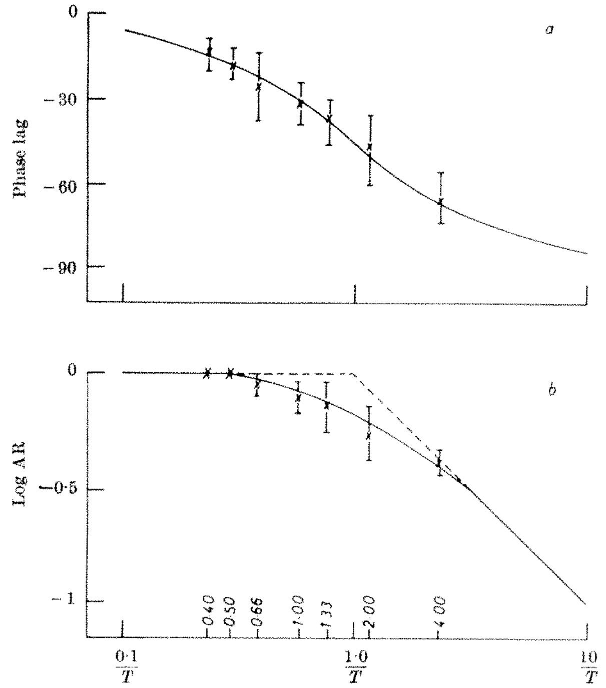

Fig. 2. Bode plot of mean response rate as a function of temperature frequency. *a*, Observed phase lag matched to that of a first-order system (continuous curve); *b*, observed compared with expected (continuous curve) amplitude ratio. Vertical lines indicate the range.

min, can be compared with a time-constant of about 2 min for the hypothalamic temperature response to a step change in ambient temperature in the 48 h water deprived Barbary dove (our unpublished results). It is possible, though we cannot yet be sure, that the drinking response is mediated by hypothalamic temperature changes, and that the increased time-constant results from the heat production caused by the work involved in the operant response.

Pheromones and their Effect on Aggression in Mice

Odours from the urine of male mice modify the sexual state of females, and this capacity has been attributed to the presence of one or more pheromones[1-4]. Male urine also possesses a pheromone which increases aggression in other male mice[5,6], but it has not been identified and its source has not been located. We wanted to know whether the output of aggression pheromone by the male is related to its agonistic behaviour, and whether the production of pheromone is androgen dependent and therefore reduced by castration. We also wanted to investigate the activity of female urine, because the precise properties of a female which permit close socio-sexual contact with a male are not clear.

Male albino mice, one hundred days old, were used. Twenty-five test mice which had been isolated for 10 days were each fought against twenty-five treated, non-aggressive, castrate opponents, and their aggressive behaviour observed for 3 min.

Pooled urine samples, taken fresh from donor mice which had been placed in metabolic cages, were applied to the coats of the castrate opponent mice, immediately before introducing them into the test cage. Urine donor categories were as follows: (1) six aggressive and (2) six non-aggressive males selected from twenty isolated males which had been fought against each other by the round-robin method[7]; (3) six bilaterally castrated males which had been operated on at 90 days of age; (4) six normal females. A fifth group of opponent mice was treated with water.

The aggressiveness of the test mouse against its regular castrate opponent was assessed by the latency period to the first attack, the number of bites and the total time spent attacking the opponent mouse. These tests were run on alternate days to blank test sessions, when the control castrate opponents received no treatment. The order of testing any group of treated mice was randomized.

Table 1. MEAN SCORES OF TEST ISOLATE MICE, ON FOUR MEASURES OF AGGRESSION, WHEN THEIR OPPONENTS WERE GIVEN DIFFERENT URINE/WATER TREATMENTS

	Source of urine applied to standard castrate opponents				
	Agg.	Sub.	Cast.	Water	Female
Latency measure					
Mean test session score with treatment	87·2	93·0	109·0	108·6	149·5
Mean change in score following treatment	−30·7*	−11·6	+2·5	11·1	+55·9*
Accumulated attack score					
Mean test session score with treatment	18·1	19·6	14·8	13·4	6·7
Mean change in score following treatment	+3·6†	+1·6	−1·04	−1·8	−10·9*
Bites score					
Mean test session score with treatment	10·0	9·9	8·4	6·4	3·3
Mean change in score following treatment	+2·4†	+1·0	−0·4	−0·7	−5·8†
No. of fights out of 25					
Number with treatment	20	16	15	13	12
Change in number following treatment	+4	+1	−4	−4	−9

Probability values (one-tailed) derived from analysis by the Wilcoxon sign test for correlated samples.

* $P < 0·025$; † $P < 0·05$.
Agg. = aggressive; sub. = submissive; cast. = castrate.

The results in Table 1 show that less of the aggression-promoting pheromone is produced in submissive than in dominant males, and none at all in castrate males. A Friedman two-way analysis of variance revealed significant overall differences between five groups (latency measure $X^2 = 12·7$, $P < 0·025$; bites score $X^2 = 11·7$, $P < 0·025$; accumulated attacking score $X^2 = 12·7$, $P = 0·025$). Our results are consistent with the findings that the male pheromones which accelerate the oestrous cycle[2] and block ovo-implantation of recently inseminated female mice[3] are also eliminated by castration. Because the male pheromone is androgen dependent, the fact that the effectiveness of submissive male urine is intermediate between that of aggressive and that of castrate males may be attributed to differences in androgen output. In this connexion we know that isolation increases both androgen output and aggression in male mice[8] and we have also found (unpublished results of N. W. N.) that dominant males, selected by the round-robin test, have significantly larger ventral prostates than their submissive fellows. It would seem therefore that aggression and aggression-inducing pheromone production are stimulated by a common factor.

Females produce a pheromone that has an oestrus-suppressing effect on other females[4]. Our results demonstrate that female urine contains a factor that inhibits male mouse aggressiveness. Without this control, presumably, sexual contact would be less successful. In sexually dimorphic species, size, colour and shape might provide the female cues for recognition by the male. We suggest that, in mice, urinary pheromones may serve this function.

We thank Mrs Angela Wouters for technical assistance and, together with Messrs Wray and Hannon, for care of the animals.

Protean Displays as Inducers of Conflict

SINCE Charles Darwin's great work of 1859, various facets of the biological armament race between predator and prey have been studied in depth, as in the work of Blest[1], Cott[2], Darwin[3] and De Ruiter[4]. These studies describe and analyse regular, predictable structure/behaviour complexes, such as camouflage, mimicry and various fleeing mechanisms.

Many animals, however, increase their efficiency as protagonists by using types of behaviours which are irregular and thereby defeat detailed prediction. We have surveyed the occurrence of such protean behaviours and defined them as behaviours which are sufficiently unsystematic in appearance to prevent a reactor predicting in detail the position and/or actions of the actor (ref. 5 and our unpublished work). The simplest and most widespread example is the single erratic display of a fleeing animal, characterized by unpredictable turns[5]. Many species, including man, will perform this display when attacked. Roeder[6] has photographed it in noctuid moths and provided evidence of its survival value[7].

The basic problem in understanding protean phenomena has been to explain how natural selection could operate in reducing the predictability of behaviour. The increase of irregularity and variety seems in part to be the opposite of evolutionary ritualization which enhances the signal value of movements or postures. In this communication we suggest that experimental psychology provides the theoretical basis which can explain the survival value of protean displays. We propose that a protean display arouses mutually incompatible tendencies in the reactor—in other words, it induces conflict. A result of conflict is lengthened reaction time[8], which must reduce a predator's chances of capturing prey.

Protean displays induce conflict in several ways. First, the predator may be presented with simultaneous stimuli, each requiring a different response, as when an attacked group of animals scatters, producing conflicting directing responses. Effects on the predator's mood may also be involved, as in the aggression of a convulsing *Peromyscus*[9]. Conflict may be similarly induced by a very rapid sequence of stimuli, each arousing a response which cannot be completed before the next stimulus has appeared and set up competing processes. Examples include a rapid single erratic display, and any distraction display involving more than one actor.

Second, the erratic nature of a protean display defeats anticipation by the predator. The more frequently stimulus events are associated in the input to an organism, the greater will be the tendency for the central correlates of one to activate the central correlates of the other[10]. Thus one stimulus may evoke preparatory responses which will allow an optimal reaction to a second stimulus. This is useful when the organism is dealing with systematically ordered stimulus systems, but protean displays seem to be highly unsystematic. Thus many preparatory responses will be wasted, or may lead to lowered efficiency by conflicting with the behavioural processes required by the new situation. This is likely when a predator is following an animal performing a single erratic display, and also when there is a change in role or position within a displaying group, as in mobbing. In its extreme form this kind of conflict appears as "surprise", which in human subjects is associated with an arrest of movements[11].

Third, when a predator is faced with the possibility that any one of several alternative stimuli is about to occur, each requiring a different response, the predator is in a state of uncertainty. Such situations involve conflict by the anticipatory arousal of incompatible responses[12]. In the single erratic display this would mean that the predator's responses with regard to direction of movement would be incompatible. Again, variations in the display given by prey on different occasions will induce conflict even in the experienced predator. If a predator has learned that its prey has various avoidance behaviours, anticipatory conflict automatically increases its reaction time.

Fourth, novel stimuli will resemble to an approximately equal extent several other familiar stimulus patterns, and by generalization will arouse certain conflicting responses appropriate to all of them[13]. The avoidance of novel objects is greatest when they have some familiar features[14]. Novel stimuli also promote uncertainty, for there is no way of knowing what will follow them. Those aspects of a protean display which are novel to the reactor therefore induce conflict. An example is the repeated flashes of bright colour during the convulsive erratic skipping of many butterflies and moths when disturbed (our unpublished work). Even a single flash of colour can delay a predator's attack[1].

The degree of conflict between competing response tendencies is determined by their nearness to equality in strength, their absolute strengths and their number[14,15]. An increase in any of these factors lengthens reaction time.

Finally, game theory[16] indicates that when two protagonists have a fairly equal chance of success, as in the "which hand is it in?" game, the best pattern is no pattern. Unpredictability is increased to the maximum possible for that particular system, the structure of which becomes protean. In the game mentioned this sets a fundamental limit of 50 per cent to predictability; this cannot be overcome by learning in the protagonist. Unlike systematic escape displays, protean displays are therefore highly resistant to learned countermeasures by the predator.

Protean behaviour embodies irregularities and stimulus variety as basic principles which increase the reactor's reaction time. This could mediate the selective advantage by which an escape display becomes protean; and the widespread occurrence of protean properties in escape behaviour suggests that they are a major factor in the biological armament race.

The Perkin-Elmer Model R12 is the highest-quality *routine* NMR Spectrometer in the world.

Perkin-Elmer has carried out a research programme for ten years on Nuclear Magnetic Resonance systems with permanent magnets. The Model R12 Spectrometer is the latest, outstandingly successful result. The unprecedented stability of its unique permanent magnet system ensures top performance – as a matter of easy, everyday laboratory routine. It meets all your requirements: unequalled performance and resolution stability, speed, easy routine operation – all at remarkably low-cost. It is easy to install and needs no special shielding from outside influences; it is augmented by a range of practical accessories. It is the instrument for every modern chemical laboratory.

Get details from Perkin-Elmer Ltd,
Beaconsfield, Bucks,
Tel: Beaconsfield 2571. Telex 83257.

Perkin-Elmer Instruments: Infrared, Ultraviolet, Fluorescence and Atomic Absorption Spectrophotometers, Gas and Liquid Chromatographs, Spectropolarimeters, Elemental and Thermal Analysers, Mass and NMR Spectrometers.

INTERSCIENCE

SYSTEM/360 JOB CONTROL LANGUAGE

by **Gary DeWard Brown,** *The Rand Corporation.*

A self-contained manual that describes the operating system facilities, such as input/output, the linkage editor, and several IBM-supplied utility programs with numerous examples to show how they can be used through Job Control Language. Can be utilized as both text and reference.

June 1970 304 pages 75s.

ADVANCES IN MATERIALS RESEARCH, Volume 4

edited by **Herbert Herman,** *State University of New York at Stony Brook.*

Gathers together articles of specialists in diverse areas of materials science. The series integrates a wide variety of scientific research in the field into a cohesive presentation for the specialist and the non-specialist alike.

June 1970 512 pages 190s.

PROCESS ANALYSIS BY STATISTICAL METHODS

by **David M. Himmelblau,** *University of Texas.*

Contains both new and standard techniques of process model building and evaluating, using statistical methods. Deals with both man-made and natural processes and emphasizes practical tools for the scientist and the engineer with which to evaluate empirical methods of processes.

June 1970 496 pages 175s.

THE ORGANIC CHEMISTRY OF TIN

by **Wilhelm Neumann,** *University of Dortmund, translated by* **Wolf Moser,** *University of Aberdeen.*

This book gives a summary and a critical review of the present knowledge of the organic chemistry of tin. It is a revised edition of the German book which was published in 1967. There are extensive alterations and several chapters have been completely re-written; about 160 new references have been included. The book is a volume in the series *The Chemistry of Organometallic Compounds*, edited by D. Seyferth, Cambridge, Mass.

due June/July 1970 approx. 290 pages approx. 110s.

PHYSICS: AN EBB AND FLOW OF IDEAS

by **Stuart J. Inglis,** *Chabot College*

Presents physics from the historical-developmental point of view. Gives descriptions of why the major developments in physics occurred, then relates them to the main body of physics. Included are discussions on the development of the physical world beginning with Aristotelian physics, moving on to the fields of electricity and magnetism, heat and conservation of energy, optics and electromagnetic waves, the four failures of classical physics and culminating in a discussion of modern atomic physics.

June 1970 464 pages 88s.

THE CHEMISTRY OF ALKENES, Volume 2

edited by **Jacob Zabicky,** *Institute for Fibres and Forest Product Research, Jerusalem and The Weizmann Institute of Science, Rehovoth, Israel.*

This book covers aspects not discussed in the first volume, edited by S. Patai and published in 1964. As in the first volume, the emphasis is on comparative critical discussion of the subjects, addressed to advanced students and research chemists. As far as possible the contributors have included all the relevant information on the recent advances regarding the theory and practice of the subject, stressing especially the theoretical, physical and mechanistic principles. (A volume in the *Chemistry of Functional Groups series.*)

June 1970 approx. 684 pages approx. 230s.

INFRARED ANALYSIS OF POLYMERS, RESINS AND ADDITIVES, AN ATLAS, Volume 1: Plastics, Elastomers, Fibres Resins, Part 1, Text

by **Dieter Hummell,** *Institute of Physical Chemistry and Colloid Chemistry, University of Cologne and* **Friedrich Scholl,** *Central Analytical Laboratory, Robert Bosch GmbH, Stuttgart.*

This work, a very much enlarged English edition of D. Hummel: Kunstoff-, Lack- und Gummi-Analysis (1958) consists of two volumes, the first of them in two parts. Volume I deals with the analysis of high polymers and resins (plastics, rubber, natural and synthetic fibres, lacquers and natural resins). The second part of this volume, containing 1,758 spectra, was published in 1969, 680s. The text which is published now gives an introduction to the principles and methods of infrared spectroscopy. It also briefly describes chemical techniques of analysis and provides tables of simple physical constants. Several physico-chemical methods (gas-, paper-, and thin-layer chromatography, pyrolytic mass spectrometry) are also treated in order to complement the spectroscopic part.

due June/July 1970 pages not yet established approx. 140s.

METHODS OF BIOCHEMICAL ANALYSIS, Volume 18

edited by **David Glick,** *Stanford University Medical School.*

The newest volume in this well-known series of reviews in the field of biochemical analysis. The series covers subjects of current importance such as chemical, physical, microbiological and animal assays, as well as basic techniques and instrumentation for the determination of enzymes, vitamins, hormones, lipids, carbohydrates, proteins and their products, minerals, antimetabolites, etc.

May 1970 416 pages 160s.

PROGRESS IN INORGANIC CHEMISTRY Volume 11

edited by **Stephen J. Lippard,** *Columbia University.*

A new volume in this important series the previous volumes of which were edited by F. A. Cotton. It reviews recent research in inorganic chemistry.

June 1970 416 pages 190s.

Nitrous Acid Effect on Cleavage and Development in Fertilized Frog Eggs

NITROUS acid causes deamination of primary amino groups attached to the ring structure of nucleic acid bases; the products have been demonstrated to cause mutations in viruses[1,2], bacteria[3], moulds[4,5] and yeasts[6]. Apart from a study demonstrating chromosomal fragmentation in monocotyledon root tips treated with nitrous acid[7], no report of HNO_2 having an effect on higher organisms has been found.

I treated fertilized frog eggs with HNO_2 and observed cleavage and development up to the feeding larval stage. The eggs, which still have jelly membranes intact, respond quickly to the externally applied HNO_2. This is advantageous, because many chemical inhibitors of development are only effective following internal injection in frog eggs[8]. HNO_2 was found to affect cleavage and development and the result is dependent on concentration and time. Furthermore, depending on the experimental conditions, the reaction of the eggs is a delayed one, for although the chemical may be removed from the eggs at one stage, the eggs do not stop developing until much later. HNO_2 may therefore have damaged nucleic acid before its expression during development.

Artificial fertilized *Rana pipiens* eggs were treated with HNO_2 solutions ($NaNO_2$-sodium acetate, *p*H 5·0) or control solutions (see Table 1). The eggs were subjected to varying times of treatment at room temperature (23°–25° C), and then rinsed in 10 per cent Steinberg's salt solution[9] and placed in about 150 ml. of this solution. Early cleavage and development up to Shumway stage 25 (ref. 9)—the feeding larval stage—were observed.

The effects of nitrous acid are enhanced as the $NaNO_2$ concentration is increased (Table 1). Controls indicate that this cannot be ascribed to the effects of *p*H, buffer alone, or sodium nitrite (legend to Table 1), but if the concentration of sodium acetate is increased at constant concentration of $NaNO_2$, cleavage and development are affected at the higher buffer concentration.

Table 1. EFFECT OF NITROUS ACID TREATMENT ON FERTILIZED FROG EGGS

$NaNO_2$ (M)	Acetate *p*H 5 (M)	Calculated HNO_2 (M)	Cleavage	Development to stage 25
0·05	0·01	0·001	0	0
0·01	0·01	0·0002	+	0
0·05	0·005	0·001	0	0
0·01	0·005	0·0002	+ +	+
0·05	0·0025	0·001	+	0
0·03	0·0025	0·0006	+ +	0
0·02	0·0025	0·0004	+ +	+
0·01	0·0025	0·0002	+ +	+ +
Control solutions			+ +	+ +

The number of eggs are indicated by: none (0), like controls (+ +), or less than controls (+). Eggs were added to solutions 1½–2 h after fertilization and treated for 3–4 h (16–32 cell stage). In each of the groups, 35–45 eggs were treated in 8 ml. of solution. Control solutions were 0·0125 M sodium acetate buffers, *p*H 5·0 and 7·0; 0·05 M $NaNO_2$–0·0125 M sodium acetate buffer, *p*H 7·0; and 10 per cent Steinberg's, *p*H 7·4. Because HNO_2 is unstable, the $NaNO_2$ solutions were made up fresh in glass distilled water adjusted to *p*H 7·1–7·3 with a weak NaOH solution. The *p*H of the HNO_2 solutions during treatment of the eggs remained within 0·1–0·2 *p*H units.

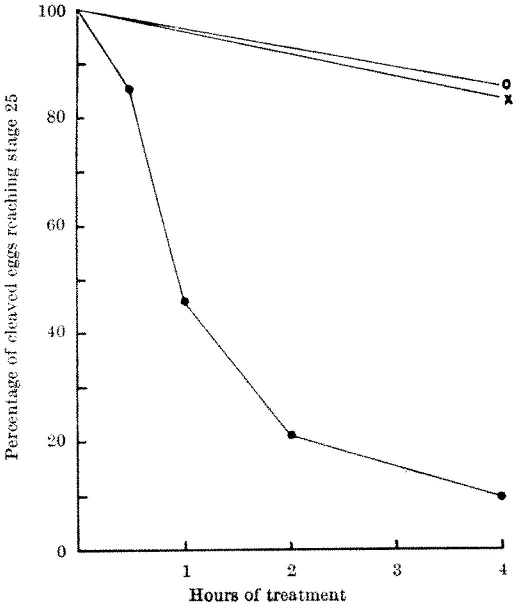

Fig. 1. Number of cleaved eggs reaching stage 25 after treatment with 0·02 M $NaNO_2$–0·0025 M sodium acetate buffer, *p*H 5·0 (●); 0·0025 M sodium acetate buffer, *p*H 5·0 (○); or 10 per cent Steinberg's solution, *p*H 7·4 (×). Eggs were added to solutions at first cleavage. 40–50 eggs were used per group.

As the length of exposure to nitrous acid is increased, fewer embryos reach a higher developmental stage (Fig. 1). A 4 h treatment with 0·02 M $NaNO_2$ caused a ten-fold decrease in the number of cleaved eggs to reach stage 25. Fig. 2*a* also demonstrates that the nitrous acid effect depends on length of treatment and concentration. Furthermore, the eggs may be treated with the chemical at one stage—early cleavage—yet development is not affected until later stages—blastula, gastrula or tail bud. A 20 h treatment in 0·01 M $NaNO_2$ resulted in a halt in development of 90 per cent or more of the eggs at the late blastula stage (stages 8–9). When these treated eggs were transferred to 10 per cent Steinberg's solution there was no further development. This is interesting because mRNA synthesis is thought to begin at an increased rate as a result of gene activation at this time in development[10].

The time in development at which HNO_2 is added to the eggs is important (Fig. 2*b*). When 0·05 M $NaNO_2$ is added to eggs 90 min after fertilization (shortly before first cleavage), all eggs stop developing immediately: yet 50 per cent of the eggs treated within minutes after fertilization for approximately the same length of time develop as far as stage 25. I have also observed that the eggs react more strongly to HNO_2 at first cleavage than shortly after fertilization: this effect might reflect easier penetration of the chemical at first cleavage.

In general, the jelly coats and egg membranes did not manifest external changes after brief exposure to solutions of HNO_2. The nature of the jelly coats does seem to affect the rapidity of the response to HNO_2 (Fig. 2*c*): eggs with jelly layers developed to stage 25 after a 10 min treatment with 0·05 M $NaNO_2$, whereas most de-jellied eggs only developed to tail bud (stage 17). The HNO_2 presumably enters eggs containing jelly layers within 30 min because some of the eggs with jelly coats treated for 30 min stopped developing after late cleavage.

Preliminary experiments indicate that in certain conditions HNO_2 may affect development of only one cell type, namely the germ cells. For example, when eggs were treated for 4 h with 0·02 M $NaNO_2$ only 10 per cent of the eggs reached stage 25 (Fig. 1). These embryos are normal in appearance except that the germ cells are significantly reduced in number. Ultraviolet treatment of amphibian eggs selectively damages nucleic acid material

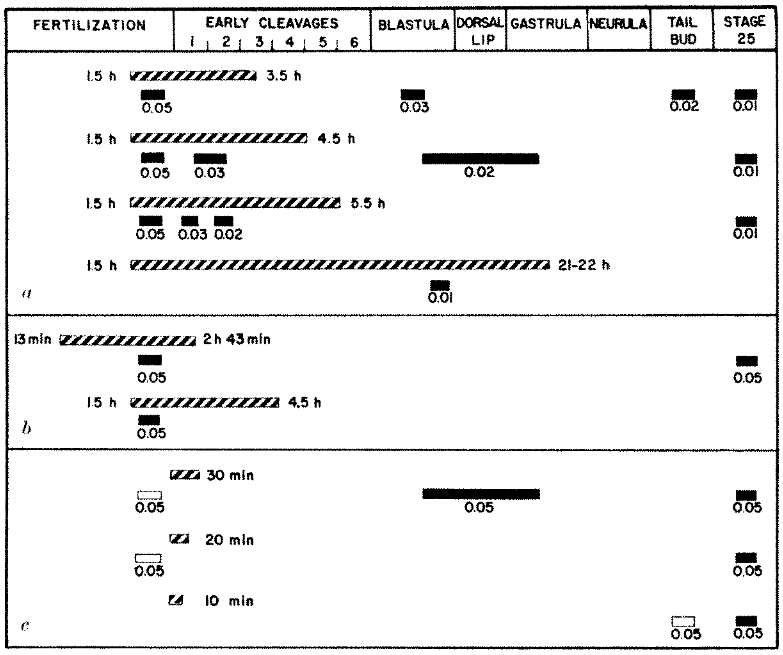

Fig. 2. Hatched areas refer to length of nitrous acid treatment. In *a* and *b* the times before and after these areas are the number of hours after fertilization when eggs were added and removed. In *c* the times refer to the duration of treatment. The black areas indicate the stage to which most ($\geqslant 40$ per cent) of the eggs developed at a particular molarity of $NaNO_2$. 0·005 M sodium acetate buffer, *p*H 5·0, was used with 0·05 M $NaNO_2$; 0·0025 M sodium acetate buffer, *p*H 5·0, was used with the other $NaNO_2$ molarities. *a*, Varying length of treatment in and concentration of nitrous acid. 40–50 eggs per group. *b*, Varying time when eggs are added to HNO_2. 40–50 eggs per group. *c*, Effect of HNO_2 on eggs with jelly coats (black areas) and de-jellied eggs (open areas). 20 eggs per group.

found in the egg cytoplasm (germ plasm) and results in normal embryos which lack germ cells[11]. Because HNO_2 affects nucleic acid, it is conceivable that one of its mechanisms of action is on the germ plasm.

I was supported by a predoctoral training grant in genetics from the US Public Health Service. This work was aided by a US Public Health Service grant, administered by R. Briggs. I thank Mrs Carole Carroll and Marion Namenwirth for discussions.

Isolation of a Protein responsible for Aggregation of Avian Embryonic Cells

CELL adhesion, as a mechanism of morphogenesis in higher organisms, has been explained by two contrasting hypotheses: first, by adhesive macromolecules[1], and, second, by a lyophobic colloid mechanism[2]. Lilien and Moscona[3] have reaggregated retina cells with a supernatant preparation taken from a culture of retina cells without, however, investigating the nature of the active compound. Electron microscopy investigations[2] have suggested that there are gaps of 100–200 Å between the plasmalemmas of living chicken embryonic cells and of many tissues of a variety of species, but were unable to find any intercellular material. We have examined the reaggregation of avian cells to identify the nature of the molecules causing reaggregation if such were found to exist.

After surgical removal, the retinas of 10 day old chick embryos were treated with 0·25 per cent trypsin (Commonwealth Serum Laboratory, Melbourne) for 10 min, washed twice in Hanks balanced salt solution and centrifuged. Then 6×10^7 of the disaggregated cells were resuspended in 8 ml. Eagle's basal medium (Grand Island Biological Co., New York) with 15 per cent foetal or young calf serum (Commonwealth Serum Laboratory, Melbourne). These were then incubated at 37° C, *p*H 7·2, for 48 h in 2 oz medical bottles. After incubation, the medium was discarded and the cell monolayers were washed three times with Hanks solution and the medium was replaced by 4 ml. Eagle's basal medium (EBM) for another 24 h. This second medium was removed and the monolayers were washed with Dulbecco "A" salt solution. To each bottle was then added 3 ml. of 0·05 M ethylene-diamine-tetraacetate, adjusted to *p*H 7·3 with 1·0 M NaOH, and after gentle pipetting to disperse the tissue, the bottles were incubated for 10 min at 37° C. The suspension was agitated, then removed and centrifuged immediately at 9,500 r.p.m. for 30 min. It was shown that the EDTA treatment did not reduce the viability of the disaggregated cells nor cause any leakage of cell components. The supernatant was freeze dried, and the dry matter was dissolved in 5 ml. of glass-distilled water and passed through a column (2·5 × 30 cm) of 'Sephadex *G*-25'. The column was eluted at 4° C with glass-distilled water and that fraction of the eluate corresponding to the excluded molecules was freeze-dried. The material was dissolved in Tyrode solution, and the protein content was determined by the method of Lowry *et al.*[4].

The biological activity of the isolated material was determined by using explanted retinas of 10 day old chick embryo disaggregated with freshly prepared trypsin (0·25 per cent) for 10 min at 37° C. Cells were counted with a haemocytometer and 5×10^6 cells placed in 25 ml. Erlenmeyer flasks containing the material dissolved in 3 ml. Tyrode solution. Each cell culture was also provided with 10 µg deoxyribonuclease[5] I (bovine pancrease; Sigma). The medium was adjusted to *p*H 7·2; the bottles were closed with a rubber stopper and placed in a gyratory shaker operated at 72 r.p.m. at 37° C. The effect of the medium on cell aggregation is shown in Fig. 1. The degree of aggregation is measured in terms of the mean log diameter of aggregates.

Although there was no significant aggregation in Tyrode solution (*A*), numerous compact aggregates were formed both in Eagle's basal medium plus serum (*B*) and with the material we prepared and refer to as retina active substance (RAS) in Tyrode solution (*C*). The effect of RAS concentration on the aggregation of retina cells is presented in Fig. 2.

The association between RAS concentration and mean log diameter of aggregates indicates that even 3 µg/ml. will induce a marked cell aggregation, while the peak value is between 30–100 µg/ml. Inhibition of cell aggregation was found at 200 µg/ml. After this concentration-dependent aggregation of retina cells had been found, we investigated the nature of the binding compound by using trypsin (lyophilized Trypsin 2 × crystallized, Worthington Biochemical Corporation, New Jersey).

RAS was treated with trypsin, at trypsin : RAS ratios of 1 : 1 to 1 : 50 at 37° C in a gyratory shaker for periods of 2, 6 or 12 h. Soyabean trypsin inhibitor (grade 1, Seravac Laboratories) was then added at twice the trypsin concentration (because of its relative impurity), and incubation continued for another hour. Finally, 5×10^6 retina cells were added after adjusting with Tyrode to 3 ml. and they were incubated for a further 24 h. The results show that trypsin treatment of 2 h did not greatly affect the activity, but the 6 and 12 h trypsin treatment eliminated the aggregating ability of the RAS. These results will be published elsewhere in detail. Control experiments indicated that neither trypsin nor soyabean trypsin inhibitor alone caused any cell reaggregation.

Recent examination of embryonic chick cell re-aggregates by electron microscopy after lanthanum staining[6] revealed intercellular material composed of fibrils. The results of our experiments suggest that protein is responsible for the adhesion of retina cells during the process of reaggregation and we suggest that reaggregation is caused by protein molecules in the intercellular spaces. In view of the extractability of the RAS with EDTA it is further suggested that the cell plasmalemmas are bridged to RAS by divalent cations.

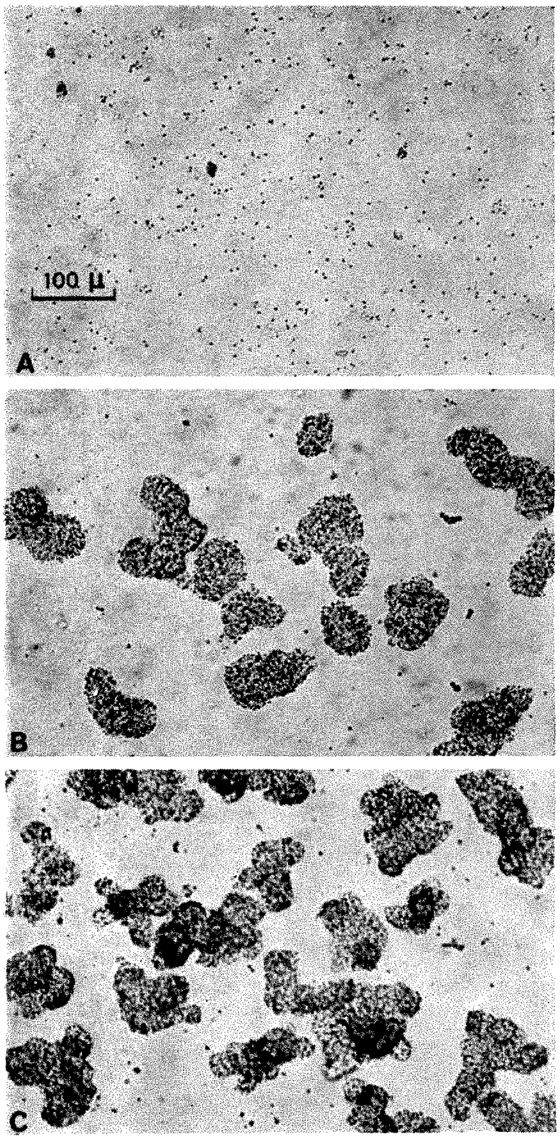

Fig. 1. The reaggregation of retina cells in: *A*, Tyrode solution; *B*, Eagle's basal medium plus 15 per cent serum; *C*, retina active substance in Tyrode salt solution (× 50).

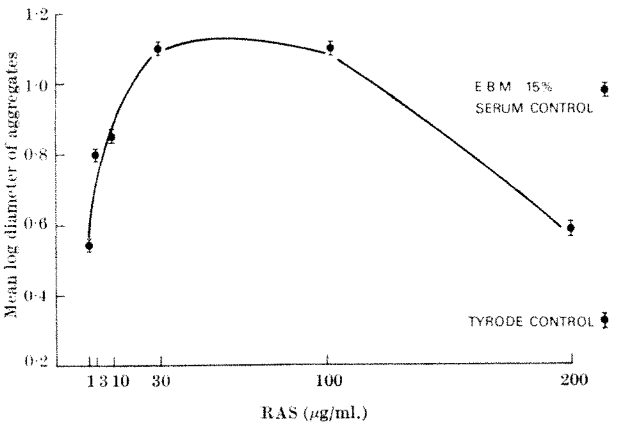

Fig. 2. Relationship between the concentration (μg/ml.) of retina active substance (RAS) and the mean log diameters of aggregates (bars denote mean and standard error).

Evidence against Transmission of Scrapie by Animal House Fomites

Accidental contamination is an abiding anxiety for all who work with scrapie agent and the possibility of false positive results is well recognized[1]. Few, however, have sought to evaluate this risk experimentally. In the light of the report by Morris *et al.*[2], we have examined the role of close physical contact and animal house fomites (sawdust, droppings, scrapers, and so on) in the establishment of the disease in normal animals.

Swiss mice—originally derived from the Moredun stock—were kept in totally separate "normal" and scrapie animal houses. All experiments were carried out in the latter and mouse adapted scrapie agent[3] was used. Animals were examined carefully twice a week, and reported on daily by animal house attendants. All findings were checked histologically (by Cajal staining of astrocytes) and by passage into further Swiss mice.

In contact experiments, normal mice were kept for more than two years in an animal house normally reserved for scrapie infected animals. They usually became old and ruffled. Ordinary scrapers were used in cleaning their cages: no particular regime was instituted, but scrapers were dipped in 'Tego' disinfectant in the usual way between cages. In a second experiment, lasting 22 months, groups of six Swiss mice were inoculated intracerebrally with 0·05 ml. of a 10 per cent suspension of scrapie brain ("10^{-1}") and put either immediately or after 14 days into groups of twenty-four C57 black mice. The Swiss mice were removed as soon as their condition was severe, care being taken to prevent them dying in the cage.

In breeding-contact experiments, animals were bred from one or two scrapie infected parents. Usually two litters, occasionally three, were obtained. Sometimes they were suckled by the original mother (if normal), but most were fostered to normal animals. After being weaned, litters were kept in the scrapie animal house for 20 months. Other litters, from normal animals, were reared from birth in the scrapie animal house.

In experiments with cage refuse the faeces and contaminated sawdust from cages of mice which had received intracerebral injections with scrapie 4 weeks previously, were transferred into the cages of normal recipient mice twice a week. This was continued until the scrapie animals were far advanced but discontinued if an animal was found dead or had been cannibalized in the scrapie cage. The experiment (with successive batches of scrapie mice) has proceeded for 20 months.

Other experiments concerned inadequately autoclaved apparatus. First, a McCartney bottle in which a whole scrapie mouse brain had been stored in about 15 ml. of 10 per cent formalin was emptied and, without rinsing, a normal brain was put into it together with 15 ml. fresh formalin. After 4 weeks this normal brain was homogenized and inoculated into mice (two separate experiments carried out). Second, an MSE macerator used for making a suspension of scrapie brain was autoclaved at 1·4 atm for 30 min once (usually this is done twice). A suspension of normal mouse brain was then prepared and inoculated intracerebrally into normal mice. Third, a suspension of 10^{-1} scrapie mouse brain was autoclaved for 30 min at 0·5 atm and then inoculated intracerebrally into normal mice. Similar experiments were carried out after autoclaving at 1·2 and 2·0 atm. In all cases titrations to 10^{-6} were carried out. The original material was similarly titred.

At no time did any mouse develop scrapie through contact with infected animals. This is true of animals which shared a cage with the latter as well as of those in separate cages within the scrapie animal house. Progeny of scrapie parents were never observed to develop the disease during 22 months, with the exception of one animal from a litter of six which was bled from the tail a few weeks after birth to test for lactate dehydrogenase level in the blood.

Animals encountering soiled litter from scrapie animals took on an aged appearance—ruffled hair, slightly hunched, slow movements, rather easily pushed over—much sooner than normal. After about a year they looked twice their age. No scrapie was detectable in any animal, however, though the astrocytes were hypertrophied (especially in the vicinity of small blood vessels) in the manner common to old animals.

The use of a contaminated bottle did not result in scrapie in the recipient mice during 2 years of observation; nor did the use of an imperfectly autoclaved macerator result in the disease. When scrapie brain suspension was autoclaved at 0·5 atm for 30 min, five of six animals injected with 10^{-1} developed scrapie, the incubation periods ranging from 8–12 months. The one remaining animal is normal. At 10^{-2}, one of six animals developed the disease after 11 months. After autoclaving at 1·2 atm, inoculation at 10^{-1} produced scrapie in one of four animals after 11 months. No scrapie developed after 2·0 atm autoclaving. Control material (not autoclaved) contained scrapie down to 10^{-6}.

In a second experiment, scrapie material (one-tenth suspension) was autoclaved for 1·3 atm at 30 min. It produced scrapie in one out of four mice after 13 months' incubation. The others are well after two years. Passage of the brain of the positive mouse produced full blown disease in 6 months. When the scrapie material was autoclaved a second time in the same conditions, it produced scrapie in four of five mice, 13, 14, 15 and 18 months after intracerebral inoculation. Again further passage of these animals resulted in the disease in 6 months. Experiments are in progress with the same material subjected to a third autoclaving process.

It is a common fear that scrapie may contaminate normal mice or experimental mice when attempts are made to establish other putative slow infections. Indeed, Morris *et al.*[2] reported the occurrence of seven cases of scrapie among two hundred normal mice which had been housed in the same room as affected mice, the disease making its appearance among the normals 18 or 19 months later. Morris *et al.* thought it likely "that virus might have been carried from cage to cage by forceps, scattered bedding, or unwashed hands, mixed water bottles or cages, or even insufficiently sterilized cages in the long period of over one year of daily handling and feeding". The experiments described here, in which healthy animals were exposed to contaminated litter, do not support this suggestion. The observations of Morris *et al.* are of the greatest importance in assessing transmission attempts so it is important to consider them critically. Unfortunately not all their "scrapie" mice were fully examined histologically, and even more important—for histological diagnosis of scrapie in old mice can be difficult or even impossible—passage was not carried out. Some doubt must accordingly attach to their results.

Fitzsimmons and Pattison[4] have reported unsuccessful attempts to transmit scrapie to sheep, goats, mice or rats by nematode parasites. Pattison[5] found that scrapie did not occur in scrapie susceptible (Cheviot) sheep or goats kept indoors in contact with a succession of affected animals; nor was he able to transmit the disease with faeces or saliva—findings which fit in well with our observations. Only when scrapie and normal animals inflicted injury in fighting did cross-infection occur —apparently from ingestion of infected fragments of tissue. Chelle[6], on the other hand, reported a case of scrapie in a goat which had been in continuous contact from birth with scrapie affected sheep. More recently, Brotherston *et al.*[7] found scrapie in ten out of seventeen goats kept for a long time in contact with sheep suffering from natural scrapie, but contact infection (in a different institute) did not occur when sheep with experimental scrapie were used as a source of infection.. Indeed, as long ago as 1954, Sigurdsson[8] presented evidence that the agent of rida (the Icelandic form of scrapie) might survive outside the host on farms where it had been prevalent and invoked an intermediate host or vector. Zlotnik[9] reported contact spread in four out of forty-two mice in 15–16 months, though the normal animals might have licked some of the inoculum leaking from the injection site. But in our study no spread was seen following either immediate contact or contact delayed for 14 days after inoculation. Contact within a cage has also been reported to result in spread[10], and Dickinson and Stamp (unpublished work cited in ref. 7) believe that lateral contagion may sometimes occur in the field.

Only Morris *et al.*[2] have reported the development of scrapie among normal animals housed with scrapie infected animals, and our work—specially designed to test for it in the worst possible conditions of contamination —has not revealed it. Animals exposed to contaminated cage litter seem to "age" more rapidly than usual but no case of scrapie has been proven histologically or by passage. We conclude that the dangers (in this particular animal house) are very small. Transmission experiments nevertheless have always been carried out in a separate animal house.

There are, however, two sources of error which may well affect long-term experiments. The possibility cannot be entirely excluded that an occasional escaped animal is replaced (instead of being killed). A wrongly labelled bottle may also be a source of error. Occasionally the disease may be inadvertently transmitted by ear-punching normal animals with an instrument used for scrapie animals[11] and infection might be carried over during withdrawal of blood by tail snipping with contaminated scissors. Handling of normal material with contaminated instruments cannot be ruled out, though direct experiment suggests that carelessness would have to be gross. On the other hand, very low scrapie titres may lead to greatly prolonged incubation periods. Recently a mouse injected with erythrocytes taken from an animal inoculated with scrapie intracerebrally 2 h previously, developed the disease after 17 months. Incubation periods beyond 6 or 7 months were found by Pattison and Jones[12], who reported that scrapie occasionally resulted from inoculation of preparations from non-scrapie brain or tumour material.

Thus we conclude that when large numbers of animals become ill with scrapie within 7 or 8 months of inoculation of a material there can be little danger in accepting the findings as valid[13]. Very long incubation may be associated with low titre scrapie and such conditions have yielded some of the most interesting findings[12]. Further contamination experiments—especially with imperfectly sterilized instruments and glassware—are therefore necessary.

We thank Mr A. Keith and Mrs F. E. Bird for their care of the animals.

Gigantopithecus and the Mountain Gorilla

PILBEAM[1] has recently described the peculiarities of the extinct pongid genus *Gigantopithecus*, and commented on the striking parallelisms between its functional morphology and that of both *Theropithecus* (following Jolly[2]) and the early Hominidae. I hope to show here that a similar functional complex has evolved in a living pongid, the rare mountain gorilla (*Gorilla gorilla beringei*).

Mountain gorillas live in the Virunga Volcanoes of the Great Lakes region of Central Africa, and on nearby Mt Kahuzi. To the west, in the Congo lowlands and in the less elevated ranges of Itombwe and Tshiaberimu, lives the eastern lowland gorilla (*G. g. graueri*); while 700 miles to the west of this subspecies occurs the western lowland gorilla (*G. g. gorilla*), living in the region between Nigeria and the lower Congo.

Table 1

	G. g. gorilla (Cameroun) ♂ Skull measurements (mm)	Sample size	*G. g. graueri* (Utu) ♂ Skull measurements (mm)	Sample size	*G. g. beringei* ♂ Skull measurements (mm)	Sample size
Cranial length	198·5	112	186·5	12	200·2	13
Maxillary toothrow	66·3	112	71·3	12	73·5	13
Palate length	117·1	112	126·3	12	134·8	13
Ascending ramus ht.	127·1	98	124·1	11	133·7	
Bigonial breadth	128·4	98	128·1	11	144·6	14
Mandibular length	204·0	98	205·6	11	206·9	14

The differences between the three subspecies concern skull characters, limb proportions, coloration and so on, and are described in a forthcoming paper[3]. The mountain gorilla, while not of much greater size than the other forms, has much larger teeth, and correspondingly more developed jaw musculature, than the western gorilla; the eastern lowland form is intermediate. A good idea of the differences can be gained from the average values[4] for male skulls (measurements in mm) in Table 1. It can be seen that *beringei*, the mountain gorilla, has larger teeth, a longer palate, higher ascending ramus and more widely flaring jaw angles than a lowland gorilla of the same

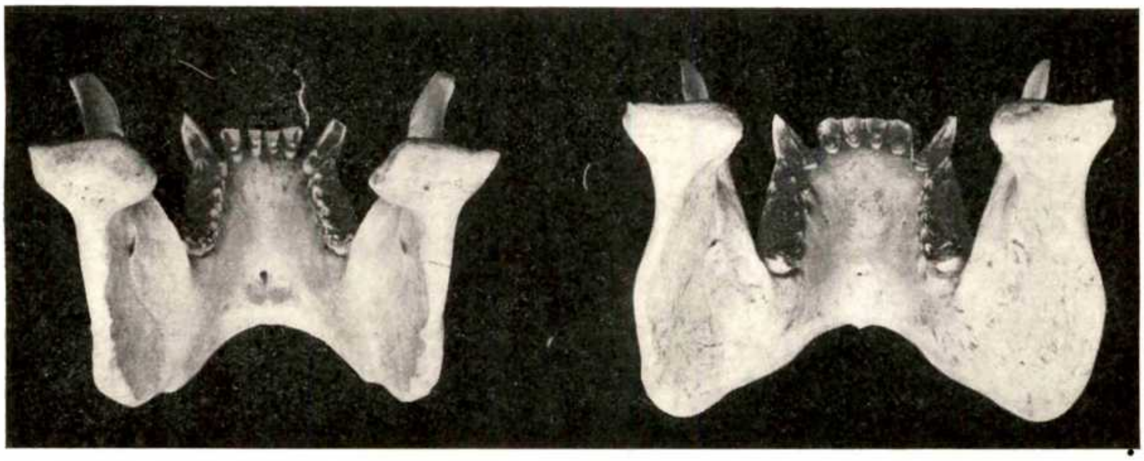

Fig. 1. Mandibles of *G. g. gorilla* (left) and *G. g. beringei* (right). Note the higher ascending ramus and more flared jaw angles of the latter. (Photo by Uno Samuelsson, Naturhistoriska Riksmuseet, Stockholm.)

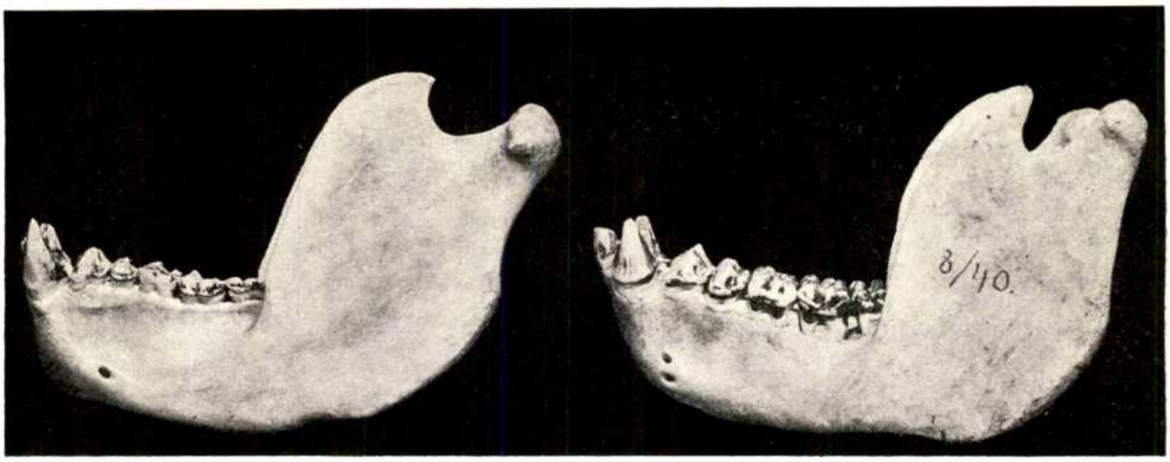

Fig. 2. Mandibles of *G. g. gorilla* (left) and *G. g. beringei* (right). Note the larger cheek teeth with higher crowns, and the higher, more muscularly moulded ascending ramus of the latter. (Photo by Uno Samuelsson, Naturhistoriska Riksmuseet, Stockholm.)

size. The eastern lowland gorilla has the large teeth and long toothrow of the mountain gorilla and a fairly long palate, but in other respects resembles its western lowland relative. The differences between highland and lowland gorillas thus to some extent recall those between *Gigantopithecus* and its dryopithecine forbears. The mandibular length of the three races also does not differ markedly, so that the long toothrow of the mountain gorilla is contained in a space no greater than that for the smaller teeth of the western gorilla. In connexion with this, Vogel[5] has observed that M_3 in *beringei* more often disappears behind the ascending ramus than in other gorillas.

Groves and Napier[6] have calculated indices to quantify the relative sizes of incisor row, canine (mesiodistal) length and molar row. Table 2 shows these indices in the mandibles of male gorillas (eastern lowland gorillas excluded). Thus the anterior teeth of the mountain gorilla, incisors and canines equally, are reduced compared with the cheekteeth just as in *Gigantopithecus*.

Table 2

	G. g. gorilla[6]	*G. g. beringei*[6]
Incisors to molars	30·3– 32·2	26·4– 30·6
Canine to molars	31·2– 37·3	29·6– 33·0
Canine to incisors	111·1–120·6	111·4–125·0

Dr Ulrich Welsch has drawn my attention to other features of the teeth of *G. g. beringei*: notably the tendency to develop extra cusps on both upper and lower teeth (5th and 6th cusps on the upper, 6th cusps on the lower), these being commonest on M^3_3, followed by M^2_2, and rare in *G. g. gorilla*. Multicuspidate molars are listed by Pilbeam[1] as distinctive of *Gigantopithecus*. The mountain gorilla tends also to have a more rounded, less sectorial form of P_3 than lowland forms—corresponding to the reduced anterior dentition. The jawbone of *beringei* is thicker, more massive and more muscularly moulded than that of *graueri* or *gorilla*[5].

According to Schaller[7], the mountain gorilla eats roots, bark and similar hard-wearing, bulky items, while in the Utu region of the "eastern lowlands", leaves and fruit are more favoured items; pith and the growing parts of the stem are eaten in both areas. The western lowland gorilla apparently eats similar foods to the eastern lowland race, and both consume a large amount of cultivated plants. The data therefore support Pilbeam's interpretation of the function of the *Gigantopithecus* morphology. The differences I have described between mountain and lowland gorillas can be said to be an intensification of those between the gorilla as a whole and the chimpanzee. The ecological and especially dietary data from the two species support this view.

Pandey and Sastri[8] have recently described a new dryopithecine species from the Siwaliks which they name *Sivapithecus lewisi*. The description indicates a large form, apparently foreshadowing certain *Gigantopithecus* traits: M_1 is high-crowned and measures $13{\cdot}9 \times 12{\cdot}1$ mm, by far the largest and marginally the narrowest dryopithecine teeth known from the Siwaliks; the canine is slightly reduced: P_3 is less sectorial, and as broad as it is long. The mandibular corpus is extremely deep and rather thick. Because posterior molars are lacking, no direct comparison with *Dryopithecus giganteus* is possible, but it may be that "*S.*" *lewisi* in fact represents this latter species, considered by Pilbeam to be ancestral to *Gigantopithecus*.

The mountain gorilla is a living member of the Hominoidea, in which direct ecological comparison with conspecifics is possible. Such comparison may help to elaborate the functional meaning of the "*Theropithecus* complex" which Pilbeam has usefully applied to *Gigantopithecus*, and which has recently[2] been applied by its describer, Jolly, to the early Hominidae; it should be clearly understood, however, that the concentration on small, tough objects—the ultimate elaboration of the *T*-complex—cannot be made to apply to *Gigantopithecus* or the gorilla, and is characteristic of man and *Theropithecus* alone.

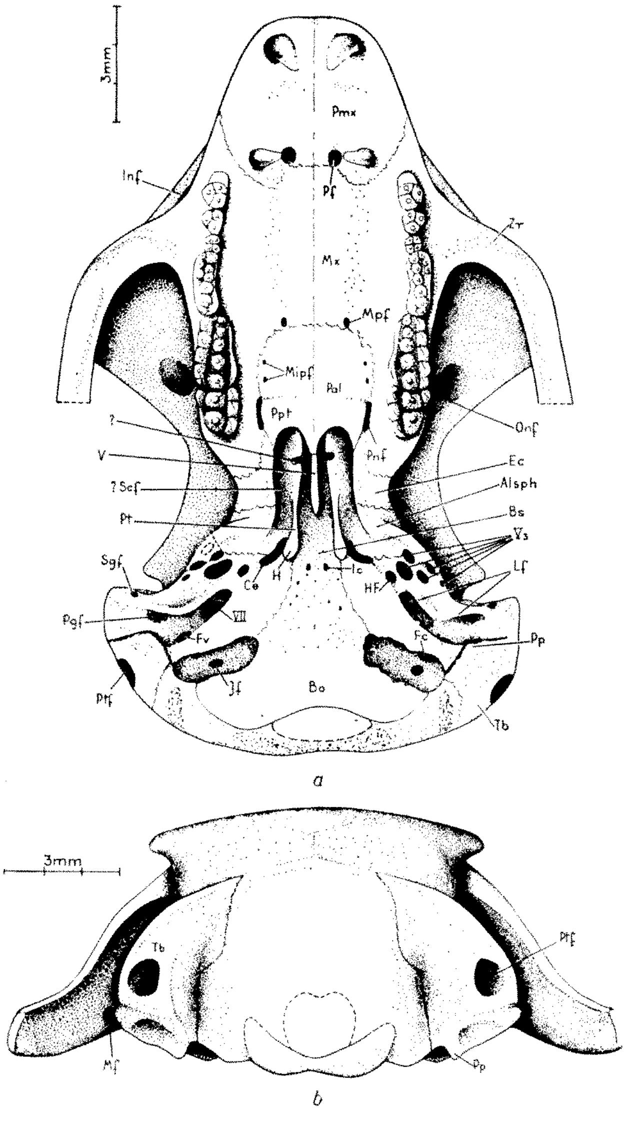
Unknown Structures in Multituberculate Skull

UP until now, no complete multituberculate skull has been known. Although skulls of two Palaeocene genera, *Ptilodus* Gidley and *Taeniolabis* Cope, are nearly complete, they both lack the lateral wall of the braincase and the occipital region[1]. Large collections of Cretaceous multituberculates recovered recently in North America through application of underwater screening techniques have yielded isolated teeth and skull fragments[2–4]. A collection of Cretaceous multituberculates has also been recovered from Bayn Dzak (Shabarakh Usu) in the Gobi Desert in

Mongolia by the Polish-Mongolia palaeontological expeditions[5]. The Gobi collection is smaller than that from North America, but it is more complete, having some entire skulls associated with fragments of the postcranial skeletons[6,7]. The age of the Bayn Dzak multituberculates is estimated as Coniacian or Santonian[6].

The type specimen of *Kamptobaatar kuczynskii* Kielan-Jaworowska[6], assigned to the Taeniolabididae, is the most complete multituberculate skull yet found. From a study of this skull, I have been able to recognize the following structures, previously unknown in Multituberculata. The pterygoids (Fig. 1*a*) do not form the lateral walls of the choanae, but are situated in the middle of either side of the choanae. Thus the choanae are divided by the vomer and the pterygoid bones into four channels. The inner channel on either side served as an air channel, while the lateral one, ending in a cul-de-sac, served as an area for muscle attachment. Lateral to the choanae there is an ectopterygoid bone. This consists of a rectangular posterior part and triangular anterior process, inserted between the palatine and maxilla. The ectopterygoid tapers at the palatonasal foramen[8]; posteriorly, it contacts the alisphenoid. There seems to be a suture between the alisphenoid and the petrosal. In the antero-lateral corner of the promontorium, presumably along the suture between the alisphenoid and the petrosal, there is a comparatively large opening which may be a remnant of cavum epiptericum. The foramen for V_3 is divided into five foramina, which probably lay along the line of fusion between the alisphenoid and the petrosal or partly within the petrosal. The alisphenoid forms a "wing", which surrounds the foramina for V_3 antero-laterally, protruding downwards over the basicranial region. The division of the foramen for V_3 into five foramina is characteristic only of *Kamptobaatar*. In other Bayn Dzak multituberculates, as in *Ptilodus*[1], the foramen for V_3 is divided into two foramina. The remaining foramina in the basicranial region in *Kamptobaatar* are more or less of the same pattern as in *Ptilodus*.



a

b

Fig. 2. Diagrammatic drawings of the lateral aspects of the braincase in *Kamptobaatar* (*a*) and in *Ornithorhynchus* (*b*). Not to scale. Abbreviations as in Fig. 1.

The lacrimal bone and lacrimal foramen are lacking in all Bayn Dzak multituberculates. The sphenopalatine foramen and the ethmoid foramen are well preserved in *Kamptobaatar*. The orbitosphenoid has a very large exposure in the orbit. It seems probable that a part of the interorbital wall was membraneous in life, and it is presumed that the large orbital fissure (see Fig. 2) passed the following nerves: II, III, IV, V_{1-2} and VI. The exposure of the perpendicular part of the palatine and of the ectopterygoid and alisphenoid in the lateral wall of the braincase is recognized tentatively. The alisphenoid is probably reduced to a comparatively small, ventral element, which does not contribute very much to the structure of the lateral wall of the braincase. Most of the lateral wall of the braincase is occupied by the anterior lamina of the petrosal, which is very extensive and irregular in shape. The squamosal has little exposure on the lateral wall of the skull, and the reconstruction of its shape in *Ptilodus* given by Simpson[1] does not seem to be very probable.

In the occipital plate (Fig. 1*b*), there is an extensive tabular which occupies the entire region between the occipital and lambdoidal crest. In the lower part of the tabular there is an unusually large post-temporal fossa. The triangular paroccipital process (in the reptilian sense) is also characteristic of the occipital region of *Kamptobaatar*.

The structures I have described show that the skull of Cretaceous multituberculates is characterized by a juxtaposition of primitive (therapsid) and advanced (mammalian) characters. The general pattern of the multituberculate braincase, in contradistinction to the opinion of Simpson[1], is essentially the same as in the monotremes (Fig. 2). On the other hand, the studied ear region and the triradiate structure of the choanal region strongly resemble those in triconodonts[9] and docodonts (*Morganucodon*)[10]. This new information on the skull structure in multituberculates confirms the opinion of Kermack[11], that the Monotremata, Multituberculata, Triconodonta and Docodonta form one subclass Prototheria, equivalent to the Theria. The Multituberculata are, however, more allied to the Monotremata than they are to the Docodonta and Triconodonta. It seems that there is no reason to place the Multituberculata in the subclass of their own, Allotheria[12], and the theory of the polyphyletic origin of mammals[13] cannot be maintained.

I thank Dr K. A. Kermack, Zoology Department, University College, London, for discussion and for placing at my disposal the undescribed specimen of *Morganucodon* from China for an examination, and Dr L. P. Tatarinov, Palaeontological Institute, USSR Academy of Sciences, Moscow, for criticism and comments.

Corophium curvispinum (Amphipoda) recorded again in the British Isles

Corophium curvispinum Sars. (Amphipoda: Corophidae) is a tubicolous crustacean which is spreading through the freshwaters of Europe, but has only been recorded twice before in the British Isles—once in the River Avon at Tewkesbury in 1935[1] (thirteen specimens), and at Stourport on Severn in 1962 (personal communication from R. W. Ingle) (sixteen specimens). In 1960, *Corophium* could not be found again at Tewkesbury[2].

Corophium has now been found in the Grand Union Canal in Leicestershire between Newton Bottom Lock (SP.631966) half a mile west of Newton Harcourt church, and at bridge 76 (SP.654941) half a mile north-east of Fleckney church. This represents a canal distance of approximately three miles. The collections were made between October 28, 1969, and February 11, 1970.

The collections have so far been concentrated on the *Fontinalis*, algae, silt and sponge debris on the brickwork of locks and bridges. The abundance and distribution of *Corophium* seem to be variable. Twenty or thirty specimens were collected quite easily at Newton Middle Lock (Spinney Lock), and at bridge 76 a hundred specimens could be picked out in a few minutes. Other collections yielded one or two specimens or none at all.

Now that *Corophium* is known to occur in the canal, a fuller survey is being made. There is also the possibility that a second species, *Corophium spongicolum*, may be found because sponges, on which it lives, are common in the locks and under bridges. Originally, *Corophium curvispinum* in freshwater was referred to as a variety 'devium'[3]. The latest opinion[4] is that two species, *C. curvispinum* and *spongicolum*, occur together in freshwater. It is difficult to understand how this animal has been overlooked until now, in view of the frequent collections that have been made over the years in the canal.

The discovery of *Corophium* in the canal was due to the recognition by a student, Miss Marion J. Gray, of a single specimen of an unusual crustacean, in a collection made by a field class from the School of Biological Sciences, University of Leicester.

I thank Dr R. W. Ingle of the British Museum (Natural History), who confirmed the identification and provided me with the latest information on the systematics of *Corophium*.

Ethylene and the Respiration Climacteric

MANY theories have been proposed to explain the nature of the climacteric rise in respiration seen in most ripening fruits. They include changes in tissue organization which lead to increased metabolism[1], or effects of mitochondria which cause a loss of respiratory control[2]. The role of ethylene in the induction of ripening has now been confirmed but, in spite of much attention, the physiological nature and significance of the climacteric have remained elusive[3]. Although fruit tissues undergo many changes during ripening[4], much biochemical organization is retained; mitochondria do not lose their respiratory control[2] and protein synthesis continues up to the climacteric maximum[5-7]. Ripening has therefore been interpreted as a process requiring considerable cellular work, so that the climacteric is merely the respiratory summation of cellular energy requirements[3]. In many fruits, however, the energy requirements for the largely catabolic events of ripening must be very small. In the banana, for example, which shows a classical respiration climacteric, starch makes up as much as 20 per cent of the fresh weight before ripening[8]. During ripening, the starch is almost completely hydrolysed by phosphorylase to sugars (an exergonic reaction). Moreover, it has been shown that the respiratory climacteric can occur in the absence of protein synthesis[6].

The respiratory climacteric seems to be almost invariably associated with endogenous production of high concentrations of ethylene[3], the ethylene evolved after ripening begins being far greater than the amount that was required to start ripening in the same fruit. Some fruits ("non-climacteric" fruits) show no clear-cut respiratory climacteric and evolve very little ethylene during ripening. If such fruits are treated with ethylene (Fig. 1*a*), however, they show a marked respiratory rise, quite like a climacteric in time and magnitude. There seems there-

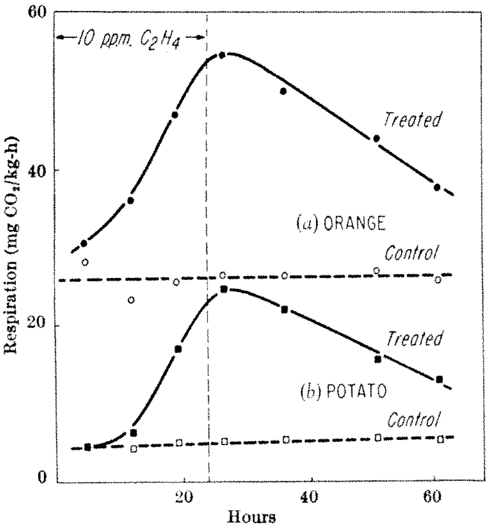

Fig. 1. Respiration at 20° C of (*a*) green mature sweet orange fruits (*Citrus sinensis*, seedling) and (*b*) mature potato tubers (*Solanum tuberosum*, cv. White Rose). The samples were held in a stream of air; ethylene was added to the treated lots during 24 h. Each point is an average of two (control) or four (treated) individual specimens.

fore to be a general association between the presence of high concentrations of ethylene and a respiration climacteric[9].

These observations support a different interpretation of the climacteric. The respiratory climacteric may be caused directly by ethylene itself at the large concentrations present in most ripening fruits, rather than by the energy requirements of other ripening phenomena. This in turn would suggest that the critical difference between the so-called "climacteric" and "non-climacteric" fruits is in the amount of endogenous ethylene produced during ripening. Although all fruits seem to be triggered to ripen by low concentrations of ethylene, only climacteric fruits show an autocatalytic production of ethylene, and consequently a respiration climacteric, as symptons of ripening.

Huelin and Barker[10] showed a small stimulation of the respiration of intact potato tubers on treatment with ethylene. We have re-examined this effect. At higher temperatures than they used, treatment of tubers with ethylene results in a very marked rise in respiration similar to that seen both in non-climacteric fruits treated with ethylene and in climacteric fruits (Fig. 1). At the respiratory peak, the respiration of treated tubers may be anywhere from five to ten times that observed in untreated tubers (Fig. 1*b*). Detailed examination of this phenomenon (unpublished work) shows other analogies to ripening fruits, particularly a marked increase in permeability. The condition of the potato, however, seems otherwise little affected by the treatment, and after a recovery period tubers will again respond to ethylene.

That treatment with ethylene of a tissue quite unlike a ripening fruit can cause respiratory effects similar to those long recognized in fruits supports the hypothesis that it may be ethylene itself that is responsible for the respiration climacteric in fruits. The potato may prove to be a useful model system for examining the role of ethylene in stimulating a respiratory climacteric in the absence of the array of other changes that occur in ripening fruits.

This work was supported in part by a research grant from the US Public Health Service.

DDT: its Action and Degradation in Bacterial Populations

A possible example of a bacterial population adapted to DDT has been reported by Henzell and Lancaster[1], who demonstrated a 50 per cent conversion of DDT in silage. In the study I report here, soil and water microflora were examined for DDT-accumulating, DDT-resistant, DDT-sensitive and DDT-degrading microbes.

DDT-accumulating organisms were detected by an autoradiographic technique[2-4]. Samples of water or soil suspension were streaked on to peptone agar with 0·8 p.p.m. ^{14}C-phenyl-DDT (specific activity 12·5 μCi/mg) in Petri dishes and incubated at 25° C. After colonies had developed, an X-ray film was placed on the agar, which had previously been covered with waterproof plastic foil (2 mg/cm^2). The film was exposed at 3° C in order to check microbial growth. After five days the film was developed and showed black spots (Fig. 1) corresponding to colonies that have accumulated ^{14}C-DDT, light spots corresponding to colonies that have not accumulated DDT and a grey background caused by radiation from the agar containing ^{14}C-DDT.

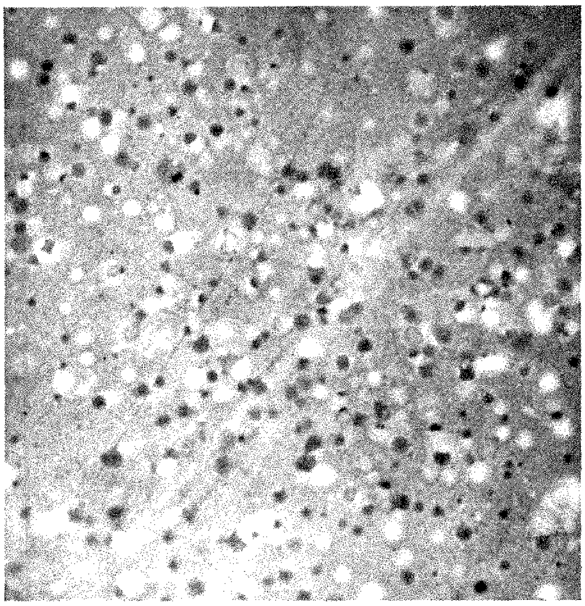

Fig. 1. Autoradiogram of peptone agar plate with 0·8 p.p.m. ^{14}C-DDT added. Black spots correspond to ^{14}C-accumulating colonies and white spots to non-accumulating colonies.

Among colonies grown from highly chlorinated Delft tap water, almost 1 per cent accumulated DDT. With polluted surface water the figures varied between 2 and 7 per cent, with garden soil samples between 60 and 70 per cent, and with nursery soil recently treated with a pesticide between 80 to 95 per cent. The percentage of DDT-accumulating bacteria was also found to be increased when other organochlorine compounds (endosulfan, lindane, simarin and captan) were applied as spray. In soil samples thought never to have been treated with any pesticide, 11 to 36 per cent DDT-accumulating bacteria were found.

The proportion of DDT-resistant bacteria in a population was estimated by a pour plate method: peptone agar containing various concentrations of DDT was mixed with a water or soil-suspension sample. The plates were incubated at 25° C. Daily colony counts showed striking differences in retardation and inhibition between two samples, of which one had been shown by autoradiography to contain 3 per cent DDT-accumulating bacteria, and the other 93 per cent (Table 1).

Table 1. DDT RESISTANCE IN TWO BACTERIAL POPULATIONS. SAMPLES ARE MIXED WITH PEPTONE AGAR CONTAINING VARIOUS CONCENTRATIONS OF DDT AND INCUBATED AT 25° C

Sample	Medium: peptone agar with DDT (p.p.m.)	Colony counts after 1–7 days expressed as percentages of the number counted after 7 days on plates with no DDT added: Days					
		1	2	3	4	5	7
Ditch water	0	7	38	78		92	100
3 per cent*	0·1	5	48	56		79	84
	1	6	36	74		89	91
	10	0	1	11		31	55
	25	0	0	0		0·5	0·5
Nursery soil	0	6	18	76	91	98	100
93 per cent*	25	0	2	12	15	16	16
	500	0	0·1	2	4	5	6
	1,000	0	0	0	0·1	0·4	0·5
	2,000	0	0	0	0	0	0

* Percentage of colonies in this population which showed blackening, as determined by the autoradiographic technique.

DDT-sensitive bacteria were detected by transferring peptone-grown colonies on to fresh plates with or without 1 p.p.m. DDT. Surprisingly, few colonies had failed to grow on these plates after three days. 5 p.p.m. DDT gradient agar plates, however, showed a definite inhibition zone. Pure cultures of the few strains which did not grow initially in the presence of 1 p.p.m. DDT could be induced to grow in two stages with 0·6 and 0·8 p.p.m. DDT.

Degradation of DDT by bacteria was investigated in pure cultures of strains selected from (*a*) strains which strongly accumulated DDT, detected by autoradiography, and (*b*) strains isolated from enrichment cultures in peptone water to which 2 per cent DDT had been added suspended in acetone. The bacteria were grown in peptone water with 1 p.p.m. ^{14}C-DDT on a rotary shaker at 25° C. After 20 h the cells were spun down, washed and extracted with methanol (once) and chloroform–methanol 1 : 1 (twice). The combined extract was put through a membrane filter, washed with 0·1 M KCl[5] and evaporated. The residue was dissolved in 5 ml. hexane and cleaned by extraction with dimethylformamide (DMF) (three times). Water was added to the combined DMF layer and DDT was left in the hexane[6]. The concentrated hexane was chromatographed on a silica gel plate with petroleum ether (40 : 60)–paraffin 4 : 1 (ref. 7). Radioactive spots were located by autoradiography and estimated with a Packard radiogram scanner. The membrane filter was also scanned for radioactivity. A recovery of 90–100 per cent was obtained from the filter and extracts combined.

One bacterial strain from group (*b*) accumulated almost 100 per cent of the radioactive material in the medium. By the methods described, 75 per cent was found in the extract and one third of this amount was chromatographically shown to have been converted into DDE. A slight amount of DDD was also present. The radioactive compounds left on the filter may be either strongly bound DDT or DDE, or unextractable degradation products.

The ubiquity of DDT—found even in Antarctic snow[8]—may explain the large proportion of DDT-resistant bacteria in all soil samples. On the other hand, its insolubility in water may explain the small proportion of DDT-resistant organisms in this ecosystem.

I thank Professor T. O. Wikén, director of the Laboratory of Microbiology, for his encouragement.

Carbon Monoxide as a Basis for Primitive Life on Other Planets: a Comment

WOLFGANG[1] has made the interesting suggestion that photodissociation of carbon dioxide to $CO + O$ may provide the necessary ingredients for a chemotrophic primary production process conducted by living creatures on other planets, analogous to the primary production function of photosynthesis on the Earth. Wolfgang cites *Bacillus oligocarbophilus* as a terrestrial precedent for biological oxidation of carbon monoxide; *Hydrogenomonas carboxydovorans*[2] is a more recently described example.

Wolfgang made his suggestion partly to emphasize the point that speculation on these matters ought not to be prejudiced towards some variant of terrestrial photosynthesis. One ought also to avoid being influenced by the prevalence of aerobic metabolism in the world around us. Wolfgang's suggestion begs many questions about the stability of the O in the particular environment being considered; such questions could be largely avoided if CO oxidation were anaerobic. CO oxidation can be coupled biologically to sulphate reduction[3] and Yagi[4–6] has shown that it couples readily to the reduction of sulphite in extracts of sulphate-reducing bacteria. I have obtained extracts of *Desulfovibrio* which conducted a rapid oxidation of carbon monoxide with sodium dithionite (normally regarded as a very strong reductant) as the oxidizing agent. Anaerobic carbon monoxide oxidation, coupled to a step in the sulphur cycle, might be intellectually a somewhat more satisfying speculation than aerobic oxidation because of the circumstantial evidence now accumulating that ecosystems based on sulphureta are present-day representatives of some of the earliest terrestrial biological systems[7–9].

Book Reviews

MAN OF MANY PARTS

Memories

By Julian Huxley. Pp. 296 + 22 plates. (Allen and Unwin: London, May 1970.) 63*s*.

WITH his tongue in his cheek, Thomas Henry Huxley once wrote in a preface to an account of his life, "Autobiographies are essentially works of fiction". Of course, his own was not fictional at all, and nor is his grandson's, for style and artistry help and do not hinder truth. It will be salutary for those who only know of Sir Julian as the leading British biologist to realize how very much more than the leading British biologist it is necessary to be in order to be the leading British biologist. Particularly interesting is the part in his life which poetry and beauty play, instilling in him much intenser feeling than any church service. Intellectually hostile to orthodox Christian dogma, he is all the more deeply religious without revelation, and rejects the excessively materialistic standpoint of certain so-called rationalists.

Many of his pages are contributions to literary history, such as the party at Les Diablerets, when Aldous's wife Maria typed out D. H. Lawrence's *Lady Chatterley* (he and Frieda were there), while Juliette typed out Julian's *Science of Life*. Then there were his experiences of that tiresome genius H. G. Wells, and his exposure of the abysmal and arrogant ignorance of Bernard Shaw in biological matters.

Julian sets high store by intuition when deciding on a line of research, and it is fascinating to see how his bird watching led through observation of common birds to the mating habits of redshank, grebe, heron, and many others, discovering the principles of ritualization and displacement activities, and the fact that the birds' behaviour can only be satisfactorily interpreted on the view that they experience emotion and fun. His work published in 1914 was a turning point in the science of ethology.

He had plenty of other lines of research: differential inhibition and re-differentiation in polyps, sea squirts, and metamorphosing sea urchin larvae; experimental embryology and the field concept; allometric growth; genetics; "new systematics" integrated with genetics and ecology, and introducing the concept of the cline, the grade and the clade; and evolution, his greatest work. He is the only Fellow of the Royal Society to have made a film ("The Private Life of the Gannet") which was awarded an Oscar.

One of the secrets of his outstanding career is his physical courage. It takes nerve to climb the back of Balliol Hall, the North Face of Trinity Clock (setting the hands wrong), the Ashmolean, and, symbol of anticipated success, the Examination Schools. This is further seen in his mountaineering; Aiguilles Dorées, Grivola, and Col du Géant in the Alps, Karissimbi in Africa. It also takes nerve when past youth to climb into the crow's nest of a 60-ton sealer on the way to Spitzbergen and to camp out there, to sail to St Kilda in a small yacht, and to run the London Zoo during the blitz. This introduces the infamous, scandalous behaviour of the old zoo council in trying, illegally, to dismiss him from the secretaryship, and then making it impossible for him to do anything other than resign.

Few biologists have had as many friends of all kinds, with whom he has practised cross-fertilization of ideas. Without mentioning any in Britain (except his better half who has helped and supported him beyond compare for more than half a century), they include all the great American biologists, Judge Holmes, Judge Frankfurter, Richard Goldschmidt, Richard Hertwig, Dohrn, de Vries, Benedetto Croce ("who looked more like a prosperous butcher than a savant"), Norbert Wiener (pioneer of cybernetics), Berg, Zawadovsky, Bukharin, Lunacharsky, and the blind and deaf Helen Keller (whose contact with the world was through the sensitiveness of her fingers) whom he saw feeling a sculpture by Michelangelo. There are not two cultures for Julian. Well does he say, "The era of solitary exploration in the laboratory or the field is now largely a thing of the past, but it was not so in my earlier days". Nor in mine.

The number of adventures that have come his way is remarkable: to be asked by a German doctor in Moscow for a copy of *The Science of Life* as a fee, and by a Lebanese pawnbroker in Kumasi for a copy of *Life and Letters of Thomas Henry Huxley* in return for some gold ornaments. He was present at a tirade by that unspeakable pseudoscientist Lysenko, Stalin's biological Rasputin, and he could "boast of having been one of the few people to have dined with Stalin in the Kremlin one night, and had tea with my wife in Hampstead next afternoon".

One of the duties of a scientist is to fight superstition, and there is a splendid description of the exposure of a medium who pretended to summon St Theresa to communicate messages from the departed. The medium was found to be in a cheese cloth, tried to hide a phosphorescent plate, and then shammed dead. He signed a confession of fraud, but within a few weeks was performing again before another audience of fools who were soon parted from their money. The obstinacy of the will to believe is itself a study.

Slightly different was the episode of Julian's advocacy of birth control on the BBC. Lord Reith abused him for having profaned "his" ether with such disgusting stuff. This topic was by no means disgusting to William Temple, Archbishop of York, who wrote to Julian, "I should cordially agree with you that birth control is just as much and just as little 'unnatural' as a pocket-handkerchief or false teeth". As Julian says, John XXIII would not have been scandalized by the report of the Lambeth conference; now the old Italian bachelor who knows no biology but decides off his own bat how hundreds of millions of men and women all over the world shall conduct their sex life, sets the stage again for the old battle between revelation and science. Julian carries on the fight which his grandfather called The New Reformation, and the spirit of Galileo, of Darwin, and of Thomas Henry Huxley still has to be vigorously defended against obscurantist superstition.

It must be a continuing source of satisfaction to Julian to see how the projects which he has either initiated or recommended are flourishing, like the Arts Council, the Council for Industrial Design, Political and Economic Planning, Planned Parenthood, the universities of Makere, Ibadan, Achimoto, Freetown, various British national parks and nature reserves, and the United Nations preparatory commission. But here I must stop, because the book does; in the sequel (to which we look forward eagerly) the world will be reminded of who it was who put the S in UNESCO.

GAVIN DE BEER

LATE LEARNERS

A History of Adult Education in Great Britain

By Thomas Kelly. Second edition. Pp. xii + 420. (Liverpool University Press: Liverpool, 1970.) 63*s*.

THIS is the second edition of a work first published in 1962. It has been enlarged by the addition of chapters on the

Second World War, the post-war pattern, and what is called "The Four-Fold Partnership"—of the central government, the local education authorities, the universities and voluntary organizations. It is a work of considerable scholarship and readers not familiar with adult education may be surprised by the wealth of literature on which the author has drawn.

The story is complicated, and many institutions and movements are described which have long since disappeared. Of those active today the universities have been longest in the field. The starting point was in 1867 when James Stuart, who subsequently became the first Professor of Mechanism and Applied Mechanics at Cambridge, began giving courses of lectures, chiefly on astronomy, to audiences in the north of England. From them developed a national system of university extension, which has continued to the present day and has shown itself to be notably adaptable to changing social and educational needs. The most recent development mentioned by Professor Kelly is the appearance of the technological universities as providers of adult education courses. Unlike the traditional universities, Bath, Strathclyde and Loughborough have established programmes of work without the assistance of special grants from the central government. That they are specially interested in applied science is significant.

While the record of the universities and the Workers' Educational Association is of continued growth, that of the local education authorities, providing for a much larger number of people, is less satisfactory. The statistics given by the author show that their adult education activities are particularly vulnerable to public economies: expansion seems inevitably to be followed by contraction. This is because their chief purpose is the education of the young, and adult education becomes the first activity to suffer when cuts have to be made.

Readers of *Nature* will be interested in the information provided about science in adult education. It started with classes in mathematics and astronomy in connexion with the study of navigation in the 16th century, produced itinerant lecturers in the 18th century, inspired the establishment of mechanics institutes in the early 19th century, and affected the foundation of university extension through James Stuart. The record was not so satisfactory in the period before the Second World War, but the number of courses in science provided by universities increased from 6 per cent of all courses in 1947–48 to 14 per cent in 1966–67. Professor Kelly points out, however, that Bristol has a much better record than any other university and indicates that this is a result of policy rather than of accident.

Science seems to be needed, however, in another respect. Many of the movements the author describes have been the result of hope and belief, rather than a careful assessment of needs, resources, and possibilities. The general expansion of education, the start of the Open University and the report of the committee now sitting under the chairmanship of Sir Lionel Russell should enable planning in the future to be more systematic than in the past.

W. E. STYLER

LANGUAGE-LACK LORE

Aphasiology and other Aspects of Language

By Macdonald Critchley. Pp. ix + 405 + 12 plates. (Arnold: London, March 1970.) 180*s*.

APHASIOLOGY is a portentous—and etymologically somewhat bizarre—word, softened on the dust cover of this book by juxtaposition with a charming picture of a pair of gannets communicating, whose previous intercourse has evidently been rewarding to judge by the chick at their feet. Within are to be found assembled all Dr Critchley's contributions on topics relating to speech and its disorders, with excursions ranging far into surrounding byways, and amusing historical touches. Comprising some quarter of a million words, this is a treasure house for anybody not wholly enslaved by a purely clinical or a coldly scientific approach to its nominally central theme.

As in all books of this kind, with varied contents written over a considerable period of time, and some inevitable repetitions, it is difficult to discern clear lines of systematic thought and committed formulation. The author does much to provide a stimulating, and corrective, context for others to think in. Topics such as the relation of animal to human communication, iterations and verbal tics, regional and demotic speech, gestural and mimic language, the details of disordered written language, the speech of psychotics and the varied significances and euphemisms for the words "Yes" and "No" should surely all form part, if peripherally, of the framework within which the neurologist, the linguist and the psychologist must try to tease out of the rich picture of clinical phenomena definite issues on which to base hypotheses suited to decisive test. Perhaps the most valuable and suggestive theme is the author's insistence on the importance of far more careful study of what he calls "minimal" aphasia. The phenomena associated with major disorders of speech are often so dramatic and compelling that theoretical views have been framed largely in terms of them, to the exclusion of what may be learnt, and perhaps more fruitfully thought about, from minor abnormalities to be found in the residual symptoms of long standing cases, in lesions exclusively of the non-dominant hemisphere and in disorders of uncertain aetiology such as "specific dyslexia" and "dysgraphia".

This is a very long book, more suited perhaps to leisure-time browsing than intensive study; sadly its price will put it out of range of many who would like it on their own shelves. Is it perhaps ironic that one who has devoted so much effort and so many words to the study and alleviation of speechlessness should now declare: "Words which should be servants now become masters. A veritable tyranny of words develops. A *pot-pourri* of clichés may eventually usurp the place of intellectualism, beliefs and judgments. Such is one of the insidious weaknesses of the structure of modern life, threatening to be an even greater menace in the future"? Can any neuropharmacologist oblige with a contralexic pill?

R. C. OLDFIELD

PATHOLOGY, PAST AND PRESENT

Trends in Clinical Pathology

Essays in Honour of Gordon Signy. Pp. xi + 352 + 4 plates. (British Medical Association: London, February 1970. Published for the Association of Clinical Pathologists.) 60*s*; $7.50.

THIS volume is a collection of essays written by distinguished British pathologists to honour Gordon Signy on his twenty-fifth anniversary as editor of the *Journal of Clinical Pathology*, the official journal of the Association of Clinical Pathologists.

Twenty-five years ago clinical pathologists were expected to be masters of most if not all hospital laboratory investigations. But new advances in medical knowledge and the increased complexity of diagnostic methods (plus the ever expanding demand for them in the National Health Service) had produced a new breed of scientific pathologist. This is readily appreciated by reference to the scope of the papers that filled Signy's journal over the years, or by reading the essays collected here in his honour.

The essays range through the major disciplines of pathology: histopathology, medical microbiology, haematology and chemical pathology to the newer clinical importance of immunology, cytology, automation and computers in the laboratory. Some contributors take a historic approach to developments in their subject over the past two or three decades, review its modern status, and speculate on future prospects. In this respect, this volume reviews a changing and expanding scene in the clinical laboratory. New developments in chemical pathology such as microtechniques related to paediatrics (Barbara Clayton) and the swing to automated computerized analysis in large central laboratories (T. P. Whitehead) are placed in perspective by N. F. Maclagan in his essay on "Chemical Pathology at the Crossroads". Haematology, present and future, is reviewed by E. K. Blackburn and J. V. Dacie, and G. H. Tovey tells a fascinating story of the developments in blood transfusion from wartime days to the presently available range of blood products. The role of microbiology in an altering disease pattern is further emphasized by J. A. Dudgeon, L. P. Garrod, Joan Taylor and R. E. O. Williams.

Other contributors concentrate chiefly on their research interest such as haemostasis (Rosemary Biggs), atherosclerosis (T. Crawford) and the relation of fibrin to hyalinosis (A. C. Lendrum). The latter two essays are accompanied by the best series of colour illustrations that I have seen in any book.

But all of the emphasis on clinical laboratory advance during twenty-five years is then brought down to earth by R. J. V. Pulvertaft, who writes on some of his experience with new and old diseases in Africa and the problems, apart from medical, facing those who investigate them.

This, by its very nature, is a once-and-for-all book, but for those who, like Signy, have lived and worked through this emergent period it presents a fascinating account of what we have and what we might expect in the future. J. L. Stafford, who organized its publication, is to be congratulated.

W. A. J. CRANE

EPILEPSY

Basic Mechanisms of the Epilepsies

Edited by H. H. Jasper, A. A. Ward and A. Pope. Pp. xxiv + 835. (Churchill: London, 1969.) 250*s*.

EPILEPSY has always been something of a mystery, but if the chief problem is still unsolved, at least this is not a subject that is standing still. Important advances in recent years have come from the electrophysiologists and electroencephalographers, in interpreting the different types of seizure pattern revealed in the clinical electroencephalograph.

The field of investigation has now been further widened, and in *Basic Mechanisms of the Epilepsies* we are presented with an encouraging range of information obtained by a variety of new techniques. The pharmacological approach has been extended by microelectrode studies of the action of anticonvulsants on individual cells. Our anatomical concepts must now include the world of ultramicrostructural detail revealed with the electron microscope, and it is significant that nearly half the chapters in this volume are dealing with neurochemical aspects of the problem.

The book started as an attempt to produce "a modern definitive statement of current knowledge regarding fundamental aspects of the epilepsies in the form of a comprehensive monograph". A meeting of experts was duly arranged at Colorado Springs, and the result is a volume of thirty chapters, to most of which has been added an additional contribution by a designated discussant. The general standard is as high as is to be expected from the very distinguished group of contributors, most of them well known in the field of brain research. The book is well illustrated, well indexed and well produced, a credit to all who have taken part. It can be recommended as the best current collection of recent information about the various aspects of brain research which have a bearing on the problem of epilepsy.

DEREK RICHTER

PATHOLOGICAL PIGMENTATION

Pigments in Pathology

Edited by Moshe Wolman. Pp. xvii + 551. (Academic Press: New York and London, September 1969.) 275*s*.

IN his preface the editor has this to say: "In various branches of science the investigator seems to pass through two phases which are distinct though intermingled. The first is a descriptive, cognitive phase in which both static and dynamic phenomena are observed and studied. These observations might be of natural phenomena or of experimental setups. The second phase is one of understanding the mechanisms involved and the implications and significance of the phenomena. A description of deposition of various pigments in different organs and tissues is of importance, even if this deposition is of no pathological or biological significance. The understanding of the various mechanisms underlying pathological pigmentation, of the implications of these processes as expressions or indications of the basic metabolic derangements, and of the deep meaning of these phenomena seem to be of greater interest and importance than the mere description. The following chapters attempt to do both to the best of the ability of the authoritative contributors."

With this clear and simple statement of editorial wisdom and intent, it becomes apparent that the contributors sailed under a sure captain. Unequivocally and without exception they have precisely fulfilled the task he set them.

After reading the opening chapter (Gedigk on "Pigmentation caused by Inorganic Materials"), the first comment I jotted down was "This is an example of a perfect chapter". It has an introduction for the benefit of the uninitiated, a middle and an end. It presents its subject clearly and concisely and pursues it without deviation in progressively greater depth, so that the reader can either follow it all the way or he can stop short and still receive a sound general coverage of it. The layout is clear, the prose is freely readable and there is a very ample bibliography. A chapter with these qualities from an author who is right on top of his subject leaves nothing more to be desired. And this opening chapter is not unique. At the end of the second (Heppleston on "Pigmentation and Disorders of the Lung"), I wrote simply "Another perfect chapter". And so it went on throughout all the sixteen chapters in the book. Some of these concern small new topics (for example, Saxén on "Tetracycline Pigmentation"), while others deal with huge and age-old subjects (for example, Liban on "Pigmented Naevi and Malignant Melanomas"). But no matter what the scope or status of the subjects, the excellence of the articles about them is the same.

To comment individually on each chapter would be a pleasure which space does not permit, and to single out a few would be unfair to the others. This book should be in every library used by pathologists and preferably in every pathology laboratory; certainly in all those where young pathologists are trained. And if a reviewer may be allowed one wish, it is that this book might be made compulsory reading for all those editors and contributors who contemplate taking part in the production of future multi-author works.

Professor Wolman and his team of authors are to be congratulated on producing an authoritative coverage of a field which has not been synthesized in this way before and on making it fascinating reading. They are also to be thanked for proving to all those reviewers, librarians and readers, who by now must inevitably have become cynical about the flood of symposium proceedings and other edited collections now being published, that such a work can be worth more than the enormous price which has to be paid for it.

I. W. WHIMSTER

DEVELOPMENTAL IMMUNOLOGY

Immunology and Development

Edited by Matteo Adinolfi. (Clinics in Developmental Medicine, No. 34.) Pp. 187. (Spastics International, in association with Heinemann (Medical): London, 1969.) 63*s*.

THIS slim volume, approaching developmental immunology from many directions, is an interesting blend of fact and fantasy. Opening with Talmage's expert account of clonal selection it presents the reader with more hypotheses per page than is usual, even in immunology. Adinolfi and Wood then contribute a thorough and elegant chapter on the ontogeny of immunoglobulins and complement in man, providing a lucid and factual account of their important research which is likely to be of considerable interest to clinician and pure scientist alike. The following chapter is more provocative. Written by Clem and Leslie, it is an entertaining review of present knowledge of the phylogeny of the immune response. Starting with speculation on immune mechanisms in plants, these authors climb the evolutionary ladder in a thorough and very readable way, pausing inevitably at the hagfish. Although pleasing to hear from them that the standards of hagfish husbandry have been improved it is saddening to be told that this fine and noble creature has been deposed from its pinnacle in immunology. It seems that it can reject skin allografts after all.

The influence of the late David Kirby on developmental immunology is clearly emphasized in the chapter by Billington on the basic immunological enigma of pregnancy. Why is the foetus not rejected as an allograft? No complete answer is available, but in reviewing the possibilities Dr Billington communicates the fascination of this problem. One can perhaps quibble with minor details of terminology, always a topic for disagreement among immunologists. The word homograft, a misnomer, is now obsolete. The term "maternal tolerance" is used several times. The phenomenon it describes is not immunological tolerance in the classical sense and it would seem safer to substitute some other expression. Billington also incorrectly assumes that the transplantability of human choriocarcinoma in a xenogeneic host implies the absence of transplantation antigens from the tumour.

A chapter by Hobbs reviews the causes of primary immune paresis in man and, although almost unreadable, it is a powerhouse of condensed factual information which could become a very useful source of reference for practising clinical immunologists and paediatricians. McConnell, in the final chapter, concentrates on another clinical aberration of immunology and development, incompatibilities of red cell, white cell and platelet antigens between foetus and mother. He provides a suitably optimistic note by emphasizing the preventability of Rh sensitization with anti-D serum.

The wide range of subjects covered and the variety of approaches to them illustrate both the fascination and clinical importance of developmental immunology. Whether one is concerned with the immunology of development or the development of immune responses this book is worth reading. Dr Adinolfi has assembled it with care. It is short, well produced and appears in a very handsome jacket.

G. A. CURRIE

INTIMATE RELATIONS

Parasitism and Symbiology

An Introductory Text. By Clark P. Read. Pp. vii + 316. (Ronald Press: New York, 1970.) n.p.

THE word symbiosis can have several meanings and Dr Read uses it in this book to describe the intimate interrelations between different species of organisms irrespective of whether the association is harmful or not. Parasitism is therefore considered as a form of symbiosis.

Parasitism is a way of life common to many plant, animal and microbial groups, but for historical reasons the phenomenon is rarely studied as a single entity. The aim of the book is to cut across artificial boundaries and to demonstrate the basic principles of the topic. In order to do this, examples are chosen from bacteria, viruses and parasitic fungi as well as protozoa and helminths. While this is entirely laudable, the breadth of the subject and interdisciplinary approach are probably too great for a single author to do full justice to all aspects of the subject. The coverage in some chapters is therefore uneven. Indeed, the preponderance of material in the book as a whole reflects the author's interest in parasitic protozoa and helminths. The chapter on the genetics of symbiosis, where microbes are adequately covered, merely underlines the scarcity of information on helminths.

The initial chapters are concerned with definitions, particularly the problems of defining the term diseases Life cycles are presented in the guise of adaptations for reaching hosts, and readers will recognize much that is already familiar in the chapter. There is a need for an entirely new approach to the dynamics of the life cycle, and the description of life cycles in terms of open feed-back loops which are closed by the host could be further developed. In this context, the recent use of systems analysis to study the epidemiology of a sheep-nematode host-parasite system is given full treatment.

The sections on adaptations for establishment in the host, nutrition, and metabolism are the best in the book, reflecting the most active areas of research in recent years.

The final chapter, symbiology and human affairs, gives an unusual insight into the impact of parasites on civilization, from the plagues of the middle ages to schistosomiasis and malaria, both so important today. The principal conclusion of this chapter is that parasitic diseases will be with us in the foreseeable future because of the plastic nature of the interaction between host and symbiote and the continual appearance of drug resistant strains or virulent mutations.

The general level of the text makes this a book for the undergraduate rather than the specialist. The layout of the book is clear with numerous subheadings and excellent illustrations. Above all, the text is very readable.

R. A. WILSON

X-RAY DIFFRACTION

An Introduction to X-ray Crystallography

By M. M. Woolfson. Pp. ix + 380. (Cambridge University Press: London, March 1970.) 85*s*; $13.50.

THE number of textbooks on X-ray diffraction is increasing rapidly, and each one now has to justify itself in some special way if it is to become generally accepted. This book falls clearly into the category of an introductory work; it ties the principles of the subject to the basic physics that the undergraduate will have learnt, and it gives enough detail for the new research student to cope with the procedures that he will be faced with. It avoids the peril of including so much theory that the newcomer to the subject will feel overwhelmed. The author is well qualified for the task; he has made significant contributions to X-ray crystallography; he is a professor of theoretical physics and hence well able to cope with some of the complexities that are glossed over in other books; and he is a good experimentalist who knows the difficulties with which the embryo research student is faced.

The book contains nine chapters—on the geometry of crystals, the scattering of X-rays, crystal diffraction, Fourier-transform theory, experimental methods, intensities of X-ray reflexions, space-group theory, determination of crystal structures and refinement. There are forty-four problems at the ends of the various chapters, carefully chosen and nicely graduated in complexity; solutions are given at the end of the book.

Of course, no author will ever accept that another's book is ideally organized, and, true to this tradition, I shall give my views on what I think are some of the deficiencies of the book and how they could be corrected in future editions.

First, the treatment of symmetry is too brief. The subject seems easy to experienced workers, but new students do find difficulties with its principles and conventions and they need a gradual introduction. A particular defect in the book is the absence of a treatment of two-dimensional space groups; symbols such as pgg are introduced later in the book without any explanation. No attempt, also, is made to show the derivation of three-dimensional space groups; they are dealt with purely descriptively. Translation itself is regarded as a symmetry element, centred lattices resulting from this operation rather than from the combination of parallel symmetry elements such as mirror and glide planes.

The section on diffraction starts off oddly, with a rather schoolboyish derivation of the diffraction pattern of a grating; the complex-exponential method would have fitted in better with the succeeding work. Also, the relation between the Fourier transform and diffraction theory is too brief; experience has shown that it needs careful exposition if it is to be properly appreciated. The same criticism applies to the introduction of the reciprocal lattice; it is treated purely as a mathematical contrivance and its basic physical meaning is not mentioned.

On the other hand, the chapters on the scattering of X-rays by atoms and the intensities of X-ray reflexions are excellent. The author shows considerable physical feeling for these subjects, and any reader who properly digests these chapters will have a better appreciation of the basic principles of the subject than many experienced crystallographers have. The theories of absorption, extinction, temperature effects and anomalous scattering are treated much more effectively than in most introductory textbooks.

The book is well produced, and the diagrams especially are beautifully conceived and drawn; the author has clearly spared no pains in expressing his ideas through them. The writing also, apart from a few grammatical infelicities, is very good and clear. The book can be recommended unreservedly to those contemplating entry into this still fascinating field of the study of crystalline matter through its diffraction of X-rays. H. LIPSON

LIQUID CRYSTALS

Liquid Crystals and their Applications

By Thomas Kallard. Pp. vi + 219. (Optosonic Press: New York, 1970.) $12.

DURING the past ten years, the subject of liquid crystals has changed from one of almost purely academic interest to one of considerable technological importance. This book now provides a source of valuable information on many of the technological applications of nematic and cholesteric liquid crystals. This is achieved by presenting detailed accounts of twenty-five patents relating to liquid crystals and their uses. These include the use of nematic liquid crystals in electro-optical devices such as valves, shutters, visual display systems, phase-matching devices for light beams, multi-frequency light deflectors, memory systems, and the like, and also of nematic liquid crystals containing dichroic dyes for colour display systems. Other patents describe the uses of cholesteric liquid crystals in devices for thermal imaging, in detecting electric fields, in detecting low concentrations of vapours, in surface thermography, for example, of skin, and in non-destructive testing of electronic circuits, laminates and so forth. Patents relating to the preparation of polarizing films and sheets, encapsulated cholesteric liquid crystals and dried emulsion coatings of cholesteric liquid crystals are also given. The contents therefore give a broad impression of the implications of liquid crystals in spheres such as medicine, television, electronics and engineering. A brief list of areas of possible future applications is also interesting.

The book does not provide basic background information on liquid crystals, but for the reader who requires this, there is presented an extensive bibliography of texts, review articles and publications relating to liquid crystals. This adds value to the text by drawing together many widely disseminated sources of information.

The reader should realize that the bibliography, while extensive, is not exhaustive, particularly with regard to literature before about 1960. The text is pleasing in presentation, but a little marred by typographical errors.

Readership should extend to chemists, physicists, medical technologists, engineers and electronic engineers. By appealing to such a broad group, the text should stimulate yet more interest in liquid crystals, and if this in turn leads to further beneficial applications, publication of the book will have been amply justified.

G. W. GRAY

HIGH ENERGY PHYSICS

Proceedings of the Fourth International Symposium on Electron and Photon Interactions at High Energies

Edited by D. W. Braben. Pp. ix + 328. (Daresbury Nuclear Physics Laboratory: Daresbury, nr Warrington, 1969.) 120s.

SCIENCE becomes ever more specialized. The first International High Energy Physics Conference (Rochester Conference) was held in 1955. At the 1960 conference a small subgroup of physicists working—or hoping to work—with electron accelerators met for one day at Cornell University to discuss their specialized topics. This became a habit; a separate symposium on electron and photon interactions was held in Cambridge, Mass., in January 1963; others at DESY, in Germany, in June 1965, at SLAC, in California, in September 1967 and now another at Daresbury, in England, in September 1969. Each occasion accelerated the coming into operation of a new electron accelerator. Many more physicists now work in this specialized field and produce exciting work. The conference was unusual in that individual papers were not read at all, but summary talks were presented, summarizing the recent work in the field including the submitted abstracts. This makes the conference proceedings easier reading for the inexpert.

A vast quantity of new information was presented on various photoproduction processes. But the exciting new information lies in three fields: inelastic electron scattering, the study of vector mesons (ω, ρ and φ) particularly in their production by electron–positron storage rings, and in quantum electrodynamics.

Inelastic electron proton scattering has been studied for some time, but Dr R. E. Taylor, of SLAC, presented his experiments on inelastic scattering with energy transfers of several BeV. Unlike the elastic electron proton scattering, and the scattering leading to definite excited nucleon states, this "deep" inelastic scattering varies only slowly with momentum transfer. This therefore describes a structure at distances smaller than the proton size. Various theoretical attempts to describe this have been made; it seems that the electrons are scattered by a small part of the nucleus; the constituent is commutally called a "parton".

The vector meson production by electron–positron colliding beams has been extended in the last year. There now exists good measurements on the ρ meson, detected by its usual $\pi^+\pi^-$ decay; the ω, detected both by its $\pi^+\pi^-\pi^0$ decay and a rare $\pi^+\pi^-$ decay; and the φ detected now by K^+K^-, $K_1^0\,K_2^0$ and $\pi^+\pi^-\pi^0$ decays. All of these give a consistent picture. The coupling of each vector meson to the photon field is measured and seems to be, within errors, equal to that assumed in the model of Vector Meson Dominance (VMD), first proposed by Sakurai, in which the ω, ρ and φ mesons are assumed to dominate the electromagnetic interactions. Dr Alcock presented one of the first experiments from the Daresbury Laboratory showing the interference between the leptonic decays of the ω and ρ mesons. Much work has been done in the past year to establish, both theoretically and experimentally, the limits of validity of the VMD model. Deviations are observed but VMD remains a very useful concept.

Experiment and theory now agree that quantum electrodynamics describes purely electromagnetic processes down to distances of the order of 10^{-15} cm. At the conference, Dr Brodsky described the recent advances; experiments of bremsstrahlung and pair production by electron and muons at high momentum transfers agree well with calculation; the difference of the g factor of the free muon from the Dirac value of 2, measured at CERN by Dr Farley and collaborators, now agrees with theory. A recent calculation of a correction term by Dr Kinoshita and collaborators—a term involving scattering of light by light—brings a new and welcome agreement. Since the conference, and therefore not in the proceedings, a recalculation of the 4th order corrections to the Lamb shift has been made, which removes another discrepancy. Everybody in the field will need a copy of these proceedings near them (till the next conference) and others would do well to read it.

Richard Wilson

NEW MATHS

A Comprehensive Textbook of Classical Mathematics

A Contemporary Interpretation. By H. B. Griffiths and P. J. Hilton. Pp. xxix + 637. (Van Nostrand Reinhold: London and New York, February 1970.) 120*s*.

This is a splendid introduction to the "new maths". "Comprehensive" is a bit grand—the material is more or less at first year undergraduate level, and the book grew from a course of lectures to school teachers, who wanted to be up-dated with the new language of sets and functions. "It has not been our primary intention to offer readers their *first* contact with the concepts and ideas we treat," so that the course is heavily didactic. The authors are not against discovery methods; the creative aspect is important, but here they are jolly well telling us how one acquires strength through unification. They have ducked the important question as to how far the new notations and treatments might be used for the actual introduction of topics, at school level, but perhaps they can reasonably argue that this is not their problem.

The book is in eight parts. The first two set up the language of set theory, and the last introduces categories and ends with a chapter on mathematical logic. In between, first, there is arithmetic, generalizing from the integers to rings with a norm. Next, there is three-dimensional geometry, introduced with vectors and leading on to linear algebra. The final chapter of this part is devoted to projective geometry. Durell would not have recognized the language, but the authors justify their "commercial" at the beginning for the excellence of projective geometry in showing what genuine mathematics is. (Incidentally, the definition of cross-ratio "where $|PQ|$ here is $-|QP|$" reads a bit strangely—this seems to arise from an ambiguity on p. 188.) Part five is devoted to algebra (groups, vector spaces, Boolean algebra, polynomials); and part six to number systems and topology (successive build-up to complex numbers and on to metric spaces).

The remaining part seven is concerned with calculus. The authors are at the same time humane teachers and puritanical mathematicians. The reader is edged forward with the spiral approach, but extrinsic motivation is minimal (the logarithm, for example, is starkly defined as an integral). But then this is a course for the already converted. Is there any danger that the fascination of compact language will lead, not to unification and clarity, but to confusion ? Certainly no schoolboy at the stage of discovering that every differentiable function is continuous is going to thank his teacher for the theorem:

> D(I) is a sub-algebra (over R) of C(I), containing the constants and the identity function I.

Will even undergraduates appreciate this particular formulation ?

But, by and large, the new look has been amply justified and agreeably presented. The above Michelin-type summary can give no real impression of the scholarship and enjoyment clearly shared and imparted by the authors.

Geoffrey Matthews

ELEMENTARY EQUATIONS

Elementary Differential Equations

By R. L. E. Schwarzenberger. (Chapman and Hall Mathematics Series.) Pp. xii + 98. (Chapman and Hall: London, September 1969.) 20*s*.

This introductory textbook is based on a course of twenty lectures given at the University of Warwick to first year students. The motivation is clear and admirable: to base the course on geometric intuition and to be concrete rather than abstract. The former is in the spirit of a great deal of contemporary research in the field of differential equations and the concrete approach achieves two objects; first, it means that the course is more directly related to school mathematics, as experienced by most pupils, and second, it leads, in a natural manner, to various abstract notions such as continuous function, vector space and linear operator.

The exposition commences with an account of differentiable functions and with some examples of differential equations. A large number of diagrams illustrate the text, this being in the spirit of the geometric approach. Then the solution of first order equations is discussed thoroughly. Possibly the most interesting and important chapter is the one relating to autonomous systems. The frequent occurrence of such systems in physical contexts is pointed out and the geometric representation of the solutions is emphasized.

The book closes with a guide to further reading, particularly in the mathematical theory, and exercises are set at the end of each chapter. The student should find the book eminently readable, and it is reasonably priced. It is refreshing, in view of the large number of texts in recent years on the subject of differential equations, to find one that is different in emphasis from most of the others.

L. S. Goddard

Correspondence

Smiles at the Unobtrusive

SIR,—A second round of supercilious comment on my quantitative estimates of scientific manpower (*Nature*, April 4, 1970, p. 10) leaves me wondering about the status of my unknown assailant. It reminds me of the regrets expressed long ago in these columns that perhaps the editor of *Nature* was being confused with its author. At all events I protest the imperious editorial attitude and remind you that the protecting shelter of anonymity carries an implied responsibility in speaking for the British scientific community. One would have no objection to a signed statement by a mere person who might find that my (or any other) social science investigation of scientists was distasteful or even loathsome. Indeed, the resistance of scientists to such intrusive examinations of themselves is well known, and though it is not pleasant, it has been a most illuminating and revealing topic of serious discussion and analysis by sociologists of science. With an unsigned editorial it is different. It surely ill behoves scientists in Britain to countenance an official attitude of this sort towards serious social science investigations into such things as the geographic distribution of scientific manpower, and any regularities and laws there might be connecting such parameters with other demographic variables. Such investigations have long exercised my respected colleagues in several countries and are hallowed by Unesco and OECD. British science policy is neither so competent and well managed nor so replete with reliable statistics that the establishment can afford just to smile at things which may be learned from these unobtrusive indicators of the deployment of our resources.

I ignored the first round of editorial humour (*Nature*, **217**, 793; 1968), supposing that its purpose was merely to amuse the readers or to draw me into a personal controversy in which opinions of scientists about science might be entertaining. My attitude towards my work is, however, not much different from that of a physicist or a chemist towards theirs. I do not publish with the principal objective of debate for an amusable public, but in the hope of adding something to knowledge before the audience of peers. If *Nature* contains on its editorial staff or among contributors those who are seriously critical and competent in the matters of estimates of scientific manpower and literature, let them speak and be very welcome indeed. The concept of a "publishing scientist" is open to a great deal of uncertainty but it gives a consistent body of reasonable laws and hopefully a rather useful analysis of a difficult problem that I would be happy to see discussed. If not, I think that the editor of *Nature* would be well advised to check the boisterousness of that part of himself that would poke fun at the antics of social scientists. The tradition of William Petty to actuarial arithmetic is not to be mocked by those who are that contemptuous of their colleagues as to think it stupid to count anything so individual and so beyond the reach of science as a human being or a "publishing scientist".

Yours faithfully,

DEREK J. DE SOLLA PRICE

Department of History of Science
and Medicine,
Box 2036, Yale Station,
New Haven, Conn. 06520.

Mediocrity of Ks

SIR,—N. W. Pirie (*Nature*, May 23, 1970) is wrong in supposing that the learned societies discriminate against alphabetical tail-enders. An inspection of the London Telephone Directory—whose subscribers we presume to be an alphabetical cross-section of London's population—has a mid-point approximately at "Kingsley" (towards the end of the Ks). This is presumably because of the infrequency of names beginning with Q, U, V, X, Y and Z.

The mid-points of the lists of members of the learned societies mentioned by Pirie therefore occur where they would be expected to (allowing for some statistical variations expected in small samples) were there no alphabetical discrimination.

Yours faithfully,

R. BROWN
R. WEST

National Institute for Medical Research,
Mill Hill,
London NW7.

Divisions among Kings

SIR,—Mr Pirie (*Nature*, May 23, 1970) suggests that there is a forward shift in the alphabet in name lists of persons recruited on the basis of apparent merit. This suggestion was based on a comparison of the list of members of the Royal Society and the National Academy of Sciences (mid-point in the Ks) with the membership lists of the Biochemical and Nutrition Societies (mid-point in the Ls). It is true that one would not expect to find selection in the latter case, and this prompted me to look in other, presumably unbiased, lists that happened to be handy, with the following results: Institute of Physics and Physical Society 1966 membership list, mid-point KING; Institute of Metals 1964/65 list, KHAN; resident members of the University of Oxford 1968/69, men KING, women KENT; the Oxford Area telephone directory 1969 (which includes businesses and institutions), KINGFEAST. The name KING is again found by opening in the middle the 3360 page *Who's Who 1958*.

The 1969 list of fellows of the Royal Society, excluding royalty and foreign members, shows that the mid-point is at KENT, so there is, after all, surely nothing to suggest that there has been any alphabetical bias in the selection of the fellowship. What is peculiar is the apparent backward shift into the Ls of the membership of the Biochemical and Nutrition Societies as reported by Mr Pirie.

Yours faithfully,

G. L'E. TURNER

46 Hamilton Road,
Oxford.

Dr Bruce and Astrophysics

SIR,—In two reports published by the Electrical Research Association in 1955 and 1958 (refs. 1 and 2) Dr C. E. R. Bruce showed that the electrification of dust in cosmic atmospheres, and the breakdown of the resulting electric fields in electrical discharges, would account for the data of astrophysics in general and the radiation from and characteristics of radio galaxies in particular. It is noteworthy that the association of the surprisingly intense radiation from quasars with dust was confirmed soon after their discovery[3], thus confirming Dr Bruce's prediction made eight years earlier. This and the theory's many other successes, many of them also demonstrably predictions, are outlined in another recent ERA Report[4], so that it is rather surprising that in their recent note Okuda and Wickramasinghe[5], while confirming Dr Bruce's suggestion as to the importance of dust in the universe, profess ignorance as to the nature of the energy source associated with it.

The novelty of many of these theoretical predictions makes their subsequent confirmation by observations all the more cogent. For example, when the highest solar temperature then discussed was only around a million degrees, Dr Bruce deduced that the temperature in solar flare discharges must reach hundreds of millions of degrees. The existence of these temperatures was confirmed by the discovery of X-rays from solar flares the following year. Dr Bruce's electrical discharge theory of solar flares would appear to have been confirmed beyond a doubt by A. B. Severny's[7] discovery, probably one of the most important astronomical observations ever made, that the transverse magnetic fields surrounding two solar flares in 1966 are such as would be caused by electric currents in the flares.

Yours faithfully,

B. C. LINDLEY

Electrical Research Association,
Cleve Road,
Leatherhead, Surrey.

Announcements

University News

Dr Robert B. Leighton has been appointed chairman of the Division of Physics, Mathematics and Astronomy, **California Institute of Technology,** in succession to **Dr Carl D. Anderson.**

Professor W. J. H. Butterfield has been appointed vice-chancellor of the **University of Nottingham,** in succession to **Professor F. S. Dainton.**

Dr M. A. Stephens, McGill University, has been appointed to the new chair of mathematical statistics, **Dr R. A. Lawrie** has been promoted to the new chair of food science and **Dr P. S. Pell** has been promoted to the second chair of civil engineering, all in the **University of Nottingham.**

Dr Eric M. Wilson has been appointed to a personal chair in hydraulic engineering in the Department of Civil Engineering, **University of Salford.**

Appointments

Sir Ashley Miles has joined the board of trustees of the **Beit Memorial Fellowships for Medical Research,** in succession to **Sir Alan N. Drury.**

The Salk Institute has appointed **Dr Frederick de Hoffmann** to the new post of chancellor. Dr de Hoffmann was the founder 15 years ago of the research laboratory known as General Atomics, since absorbed by the Gulf Corporation and now known as Gulf General Atomic.

The **British Nutrition Foundation** has announced the creation of two new offices, to replace that of director-general, held by Dr Alastair Frazer until his death last June. **Professor F. G. Young,** University of Cambridge, has been appointed president of the Foundation (a part-time position), and **Miss Dorothy Hollingsworth,** who is at present head of the Food Science Advice Branch of the Ministry of Agriculture, Fisheries and Food, will become full-time director of the Foundation in August.

Miscellaneous

The Duke of Northumberland has been elected a Fellow of the Royal Society, under that statute which provides for the election of persons who either have rendered conspicuous service to the cause of science or are such that their election would be of signal benefit to the Society.

Awards from the **Ethel Behrens Fund** are available to Fellows of the **Chemical Society** who are studying for their first degree at a British university or technical college, to assist with maintenance and travelling expenses incurred in attending the annual meeting of the Society. This meeting will be held in Brighton from March 31 to April 3, 1971. Further information can be obtained from the Scientific Affairs Officer of the Society, Burlington House, London W1V OBN.

Twenty grants from the **Chemical Society's Research Fund,** each of £50, will be awarded to Fellows of the Society for the year 1971. Applications will be considered on a merit basis, but preference will be given to those working in less well endowed establishments. Further details can be obtained from the Administrative Officer, The Chemical Society, Burlington House, London W1V OBN.

ERRATUM. The contents entry for the article by N. R. Blacklow and A. Z. Kapikian "Serological Studies with EB Virus in Infectious Lymphocytosis" (*Nature*, **226**, 647; 1970) should have been **Infectious lymphocytosis,** not **Infectious mononucleosis.** In the article itself, five lines from the end, read "these children" not "three children".

International Meetings

June 29–July 3, **The Harnessing of Science and its Application to Assist in Day to Day Management,** London (Derek Osborne, Operational Research Society Ltd, 64 Cannon Street, London EC4).

July 1, 8, 15, 22, 29, August 5, 12, 19, 24, 26, **Will Rogers' Teaching and Training Institute Summer Seminars,** Saranac Lake, NY (Montague Memorial Library, Will Rogers Hospital, Saranac Lake, NY, USA).

July 15–17, **Testing Fibrous Composites for Mechanical Properties,** Teddington (Dr S. L. S. Thomas, National Physical Laboratory, Teddington, Middlesex).

July 20–24, **The Mechanisms of Reactions in Solution,** Canterbury (Dr J. F. Gibson, The Chemical Society, Burlington House, London W1V OBN).

July 22–24, **Water Pollution Control in Cold Climates,** College (Dr R. Sage Murphy, Institute of Water Resources, University of Alaska, College, Alaska 99701, USA).

July 26–August 1, **Water Pollution Research,** San Francisco (IAWRR Registration Headquarters, Room No. 635, Davis Hall, University of California, Berkeley, California 94720, USA).

August 5–7, **Applications of X-ray Analysis,** Denver (Metallurgy and Materials Science Department, Denver Research Institute, University of Denver, Denver, Colorado 80210, USA).

Sabbatical Itinerants

In the hope of providing some practical assistance in the good cause of mobility between laboratories, *Nature* advertises the needs for housing of families about to take up periods of sabbatical leave. To begin with, no charge will be made for advertisements like this. It is hoped that a period of experiment will show what form these advertisements could most usefully take and whether they are effective.

Wanted: Furnished 3 bedroom house in or near Cambridge for one year from August 1970. Prefer something with character rather than a modern development; will consider up to 10 miles from city centre. **Vacant:** 3 bedroom house near University of California at Irvine, for rent or **exchange** during same period. Please contact Dr C. J. Brokaw, Division of Biology, California Institute of Technology, Pasadena, California 91109, USA.

Wanted: From August 20 for 12 months, furnished flat or house with 2 bedrooms in London with easy access to the University of London, for American professor and family (3 children). Please contact Professor Jack K. Ward, Director of the Computer Center, Westminster College, Fulton, Missouri 65251, USA.

Wanted: From July 15 or August 1, 1970, until August 1971, 4 bedroom accommodation for Canadian professor, wife and 4 school age children convenient to King's College, London. Please contact Dr D. D. Betts, Physics Department, University of Alberta, Edmonton, Alberta, Canada.

Wanted: Furnished house for professor and family with three boys, in or near Cambridge, for one year from mid-August. Please contact Dr W. K. Honig, Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada.

Vacant: From September 1970 for 1 year (longer by arrangement), beautifully furnished, 1 bedroom, fourth floor flat (no lift) in modern block in London, W11. Please contact Dr Nigel Godson, Department of Radiology, Yale Medical Center, New Haven, Connecticut, USA.

Vacant: Furnished one-bedroom flat with kitchen and bathroom. 2 minutes from Highgate Hill. Available immediately. Please contact Frank House, 33 Ardoch Road, Catford, London SE.

Vacant: From mid-August 1970 to end June 1971, furnished country house, partial central heating, three bedrooms, 7 miles from University of Edinburgh. Please contact Dr M. Lunan, ESR Division, FAO, Rome, Italy.

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

***12 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire.................................**£14.0.0** each
United States of America........(by air freight)..........**$48** each
Canada..........................(by air freight)........**$52** each
Elsewhere overseas by surface mail...................**£14.0.0** each
(Charge for delivery by air mail on application)

*Shorter periods *pro rata*. (Minimum three months.)

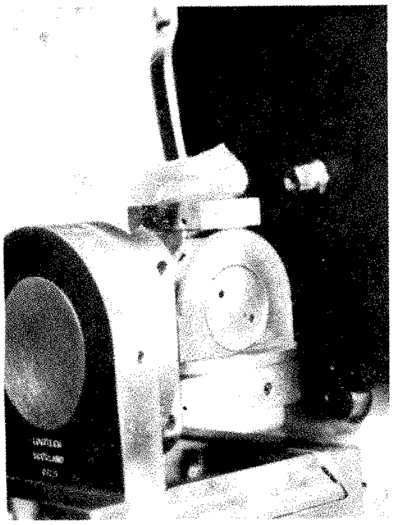
Let us SHAPE UP to your POLISHING PROBLEMS

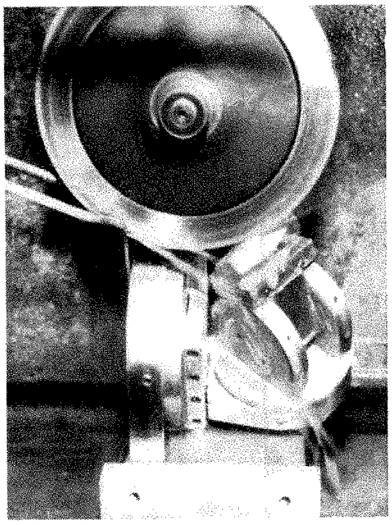
(...and others)

LOGITECH specialise in the production of versatile precision equipment to help solve the orienting, cutting, shaping, lapping and polishing problems of modern materials technology.

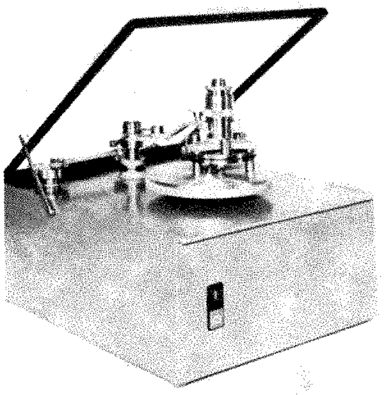
Our range of sophisticated equipment includes



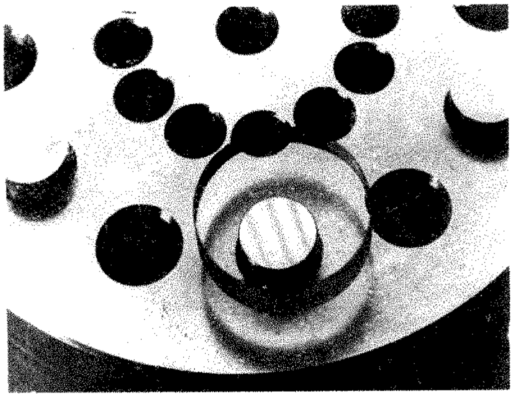
OJ2 orientation jig with crystal in position for x-ray analysis.



Cutting and grinding along chosen planes after angular adjustment.



PM2 precision lapping and polishing system.



and they give results like this.

If you are involved in Research and Development on material preparation of metals, non-metals, single crystals or polycrystals, clip out the coupon below and post it to us. We'll send you our detailed product catalogue.

And that's the beginning of the end of your problem.

13 mm diameter rods with ultra flat polished ends.

CSIRO

REPRODUCTIVE PHYSIOLOGIST

AUSTRALIA

DIVISION OF ANIMAL PHYSIOLOGY

GENERAL The Division of Animal Physiology of the Commonwealth Scientific and Industrial Research Organization wishes to appoint a Reproductive Physiologist to its Beef Cattle Research Section. Initially the appointee will work at the headquarters of the Division at the Ian Clunies Ross Animal Research Laboratory, Prospect, N.S.W., where there are active groups in the reproduction, nutrition and endocrine fields. The final location of the appointee will be in Queensland. CSIRO already has several research teams working in north-Eastern Australia. The biological problems associated with the northern cattle industry are numerous and these provide a challenge for scientific research. Currently the Beef Cattle Research Section is closely associated with the Division of Tropical Pastures which has major laboratories in Brisbane and Townsville where good facilities exist for reproductive physiology investigations.

DUTIES A research scientist is required to investigate physiology of reproduction in beef cattle maintained in tropical and sub-tropical environments. In particular the appointee will investigate reproductive performance of beef cattle especially in relation to nutrition. He will not be required to work on infectious diseases of cattle but will be expected to maintain close contact with those working in this field.

QUALIFICATIONS A Ph.D. degree or postgraduate research experience of an equivalent standard and duration in the field of mammalian reproduction, supported by satisfactory evidence of research ability. Experience in the tropics and familiarity with beef cattle production are not pre-requisites.

SALARY Depending upon qualifications and experience, the appointment will be made within the salary range of Research Scientist, $A6,139–$A7,789 p.a., or Senior Research Scientist, $A8,105–$A9,448 p.a. For an outstanding appointee a higher classification will be considered. Salary rates for women are $A428 p.a. less than the corresponding rates for men. Promotion within CSIRO to a higher classification is determined by merit.

CONDITIONS The duration of the appointment will be determined in consultation with the successful candidate; some applicants may prefer a fixed term appointment for three years. The appointment will be conditional upon passing a medical examination and an initial probationary period of twelve months may be specified. An indefinite appointment carries with it Commonwealth Superannuation Fund or Provident Account privileges.

Applications (quoting Appointment No.: 245/472), and stating full name, place, date and year of birth, nationality, marital status, present employment, details of qualifications and experience, together with the names of not more than four persons acquainted with the applicant's academic and professional standing, should reach:

Mr. R. F. Turnbull,
Chief Scientific Liaison Officer,
Australian Scientific Liaison Office,
64-78, Kingsway,
LONDON WC2B 6BD
by the **3rd July, 1970.**

Applications in U.S.A. and Canada should be sent to The Scientific Attaché, Australian Embassy, 1601 Massachusetts Ave. NW, WASHINGTON DC 20036.

(2214)

UNIVERSITY OF BELFAST

TEMPORARY ASSISTANT LECTURESHIP IN ZOOLOGY

The Senate of The Queen's University of Belfast invites applications for a Temporary Assistant Lectureship in Zoology from 1st October 1970 to 30th September 1971. Applicants should have interests in aspects of invertebrate biology. The salary will be at an appropriate point on the scale £1,240 to £1,470 (under review), depending on the qualifications and experience of the successful candidate.

One copy of a letter of application, giving the names of two referees, should be sent to the Secretary, The Queen's University of Belfast, Belfast BT7 1NN, Northern Ireland (from whom further particulars may be obtained) by 30th June 1970. (2265)

UNIVERSITY OF LEICESTER

DEPT. OF PSYCHOLOGY

S.R.C. RESEARCH ASSISTANT

Applications are invited to assist in a project on :

(1) Social behaviour and display in ducks.
(2) Colour vision in birds.

The appointment will be from August 15, 1970, and in the first instance runs for one year until September 30, 1971. Honours degree and some research experience expected. Salary scale up to lectureship level, depending on qualifications.

Applications, with curriculum vitae under names of three referees, should reach: Dr. U. Weidmann, Dept. of Psychology, University, Leicester, before June 14. (2240)

UNIVERSITY OF NEW ENGLAND

ARMIDALE, NEW SOUTH WALES

SENIOR APPOINTMENTS IN GEOGRAPHY

The Department of Geography proposes to make two appointments during 1970. One of these will be to a

CHAIR OF GEOGRAPHY

and the other to a

LECTURESHIP OR SENIOR LECTURESHIP IN GEOGRAPHY

One of these vacancies is a newly-created post, the other a replacement appointment. The new professor will fill the second chair in the Department, and it is envisaged that he will be, for a period of time, Head of the Department, alternating in this position with the present Head of the Department, Professor Gilbert J. Butland.

The principal academic needs of the Department, which it is hoped the new appointees will fill, are in the fields of Geomorphology, Regional Planning and South-East Asian Regional Geography, but of greater importance than these specific specialisms is the academic excellence of the applicants, no matter what their special interests are, as the appointees will be encouraged to develop teaching courses related to their research interests.

In addition, in view of the creation of the School of Natural Resources in the University, it is hoped that the Department of Geography will contribute to the development of the new School in the academic offerings of the two appointees in the fields of Hydrology and Regional Planning, in both of which the Department has already made a substantial beginning. It would be especially welcome, therefore, if the new Professor would build a strong, specialist team in one of these two directions, so that the Department's support of Natural Resources in aspects of environmental design, regional development, water resource utilisation and/or hydrogeomorphology would not only be significant but emphasize the applied nature of the geographical studies taught and researched within the Geography Department.

Preference will also be given in one of the appointments to applicants with field experience in South-East Asia, and with interest and competence in the construction of courses in the geography of that major world region.

Applications close on June 25, 1970.

LECTURER—DEPARTMENT OF BIOCHEMISTRY AND NUTRITION

The successful applicant may be required to teach Biochemistry to second year Rural Science and Science students and to third and Honours year Science students. First class facilities are available for research in most pure and applied fields. These facilities include a well-equipped radio tracer laboratory for hard and soft emitters, mass spectrometer, several gas liquid chromatographs with radio active monitoring system, spectrophotometers, automatic analysing equipment including amino acid analysers, infra-red spectrophotometers and a wide range of the usual laboratory equipment. The successful applicant would be expected to do independent research, either individually or in collaboration in studies at present being undertaken in the Department.

Applicants should have a Ph.D. degree and would be expected to take up their appointment early in 1971

Applications close on June 30, 1970.

Salary ranges: Professor, $A12,000 per annum.
Senior Lecturer, $A7,600 by $A230 to $A8,750 per annum.
Lecturer, $A5,400 by $A270 to $A7,020 by $A280 to $A7,300 per annum.

Conditions include provision for travel and removal expenses, superannuation, assistance in buying or building a home, and study leave. Study leave grants are available and credit may be granted for existing study leave entitlement.

Further information may be obtained from the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, WC1H 0PF.

(2279)

For further Classified advertisements see page x

THE POLYTECHNIC OF CENTRAL LONDON

Applications are invited for full-time posts as

RESEARCH ASSISTANTS in PHYSICS

duties to commence in September/October, 1970. The research will be either in the field of Vacuum Physics or Radiation Physics.

Candidates should possess a good Honours Degree in Physics. Students expecting to graduate this Summer are invited to apply.

Salary scale: £930 by £30 (2) to £990 per annum.

Applications should be made in writing to the Head of the Department of Mathematics and Physics, The Polytechnic of Central London, 309 Regent Street, London, W1R 8AL. (2225)

THE BRITISH COUNCIL

ARGENTINA

THE NATIONAL UNIVERSITY OF THE LITORAL, SANTA FE requires a PROFESSOR OF UNIT OPERATIONS (Food Processing) as soon as possible. Candidates men only, should have an M.Sc. degree from a university in Britain, teaching and research experience, and published work. A Ph.D. degree would be an advantage. A basic knowledge of Spanish on arrival at post is essential.

Salary: £2,850 to £3,750 per annum according to qualifications and experience. Overseas allowances within the following ranges: married (accompanied) £941 to £700, married (unaccompanied) £646 to £395, single £12 to nil. Children's and home education allowances. Income tax refunded if levied. Free furnished accommodation. Outfit grant. Employer's superannuation contribution paid. Medical and insurance schemes. Fares paid for Professor and family, including mid-tour passages for children in Britain. Two-year contract guaranteed by the British Council.

Write, quoting reference number 9/OU94 to Appointments Division, The British Council, 65 Davies Street, London W1Y 2AA, for further particulars and application form to be returned completed as soon as possible. (2226)

UNIVERSITY OF EDINBURGH

DEPARTMENT OF FORESTRY AND NATURAL RESOURCES

Applications are invited for the post of RESEARCH FELLOW or RESEARCH ASSISTANT in the above Department to work on hooded crows in West Scotland. Duties will be to initiate and develop a study of the feeding ecology of hooded crows, and more specifically, their relationship to hill sheep; and to co-operate in a population study. Applicants should be graduates in a biological subject with field experience of birds or mammals and a good understanding of ecological processes. The successful candidate will be expected to work from Oban, Argyll and ability to drive is essential. The post is tenable from 1st October, 1970, for three years.

Salary will be in the range £1,000 to £1,600 per annum depending on qualifications and experience, together with F.S.S.U.

Applications (two copies), giving the names of two referees, should be sent to the Secretary to the University, Old College, South Bridge, Edinburgh EH8 9YL. Please quote reference 5020. (2266)

HOUGHTON POULTRY RESEARCH STATION, HOUGHTON, HUNTINGDON

(Grant-aided by the Agricultural Research Council)

Applications are invited for the following posts in the grades of

SCIENTIFIC OFFICER OR SENIOR SCIENTIFIC OFFICER

(i) ELECTRON MICROSCOPIST

in the Leukosis Experimental Unit

Applications are invited from medical, veterinary or science graduates with experience or an interest in electron microscopy. The successful candidate would join a group studying avian virus tumours with particular emphasis on Marek's disease, and would be responsible for a small electron microscope unit. The work would include ultrastructural characterization of the lesions of Marek's disease and collaborative studies designed to develop techniques for the concentration and purification of Marek's disease virus.

(ii) VIROLOGIST

in the Virology Department

to assist in an investigation of avian respiratory infections. The work will entail studies on the incidence of respiratory disease in poultry flocks and investigations into the characteristics of viruses found to be involved.

Veterinary qualifications desirable but not essential.

Excellent facilities in both posts for experimental work and opportunities to work for a higher degree.

The appointment will be made in the scientific officer or senior scientific officer grade according to age, qualifications and experience. Salary scale: £1,162 to £1,982 or £2,193 to £2,703. F.S.S.U. superannuation.

Further particulars and application forms from the Secretary, Houghton Poultry Research Station, Houghton, Huntingdon, to whom completed application forms should be returned by July 17, 1970. (2256)

UGANDA

TECHNICAL OFFICER

required by the Medical Research Council for their Child Nutrition Research Unit, Kampala, Uganda.

The Unit is studying nutrition and its disorders in infancy and childhood by several means, especially biochemical. The Unit consists of a metabolic ward, a series of laboratories containing modern, automated equipment, a newly built primate house and out-patient clinics. The successful candidate would be expected to become responsible for the general running of the primate house. He would preferably have experience in microbiology and in routine biochemistry. The qualification required is Higher National Certificate or its equivalent.

This post is newly created and is immediately available.

Appointment initially for a tour of 30 months at a salary on scale rising to £2,192, plus overseas allowances of up to £1,125 (married) and £570 (single). Education allowances and two free passages a year for children at U.K. Boarding Schools. Contributory Superannuation. Free furnished accommodation. Full details of conditions of service will be given at interview.

For further information and an application form please write to Mr. E. P. Aboud, Personnel (Overseas), Medical Research Council, 20 Park Crescent, London W1N 4AL, quoting N240/260.

(2230)

ETHICAL PHARMA

One of the world's leading ethical pharmaceutical manufacturers, wit fine record of research over more than 40 years, wishes to make the following important appointments at its headquarters in the Netherlands. The reputation of the company has been built on worldw acceptance of its range of ethical products, originated by research an development teams with a total staff of more than 600. These scientis are drawn from many countries, including a number from the U.K.

SENIOR PATHOLOGIST

c£5,500

A Senior Pathologist is required to take charge of the histopathology laboratory which performs an important part of the company's drug safety evaluation work.

A first-class background in veterinary or medical pathology is required, preferably with experience gained during toxicity trials.

The department deals with a high volume of work, and candidates must be experienced in lucid report writing and data presentation. The department is well staffed at both scientific and technical levels.

Age is not important, but candidates must have appropriate postgraduate qualifications as well as substantial experience.

SENIOR PHARMACOLOGIST

c£5,000

CARDIOVASCULAR RESEARCH

The Department of Pharmacology has primary interests in the cardio vascular, anti-inflammatory and central nervous system fields, and the future development of drug research in these areas requires the appointment of two additional Pharmacologists.

The department is exceptionally well equipped and backed by experienced supporting staff. Collaboration with other research disciplines is close, especially with the department of Basic Human Research, which offers opportunities for clinical contacts. Cordial relations are maintained with a number of important university departments of pharmacology, and publication of results and attendance at scientific meetings is actively encouraged.

The Senior Pharmacologist will take charge of the cardiovascular group and post-doctoral experience in the analysis of drug action in this field would be a definite advantage.

The successful candidate is likely to be in his early 30s and will have probably graduated in medicine, physiology or pharmacy. His postgraduate experience will have led to the award of a PhD, M.D. or equivalent in pharmacology. This appointment will appeal to a young but mature pharmacologist, whose record of achievement shows that he has the professional capability, energy and enthusiasm to lead a specialist group.

PHARMACOLOGI

c£4,000

NEURO-PHARMACOLOGICAL RESEARCH

This appointment will appeal to a Pharmacologist with a basic intere the functioning of the central nerv system. He should be capable of initiating and maintaining a researc programme within a group devote the exploration of new approaches therapy of nervous dysfunction.

The successful candidate, who is li to be in his late 20s, or early 30s, m have graduated in medicine, physi or pharmacy, and will have comple postgraduate studies to at least Ph MD level, preferably in neurophar cological or physiological research.

CONDITIONS OF SERVICE. The company's salary policy allows for ample recognition of merit and conditions of service and fringe benefits are excellent.

TRAINING AND DEVELOPMENT. The company offers training and development opportunities to all its staff, and encouragement is given for attendance at scientific meetings, and for publication of results.

LANGUAGES. English is freely spoken by all management and scientific staff, and additional facilities are available for learning other European languages.

LOCATION. All these appointments are located at the company's headquarters, which provides a pleasant country town environment with good housing, education and recreational facilities. The company will provide every assistance with removal and relocation.

We hope to be the least successful team in Mexico

When you have been given the job of carrying out the drug-tests for the World Cup series, you do not really want much success – in fact we will be highly delighted if all the tests prove negative. But naturally we are proud that, just as for the 1968 Olympic Games, two Pye Unicam instruments have been selected for this important task – a Pye Series 104 Chromatograph and a Unicam SP700 Spectrophotometer. These high precision instruments are capable of detecting artificial stimulants in concentrations as low as 0.2 µg/ml of urine – which in itself should prove an effective deterrent.
So with any luck we might not have to interrupt our siesta. And may the best team win – as long as it's England!

Keeping on the Straight and Narrow Path

EVERYBODY is anxious to give the Food and Drug Administration a fair chance to prove that it can rise like a phoenix from the ashes of its old reputation, and there is every sign that the new Commissioner, Dr Charles Edwards, is beginning to make a mark. This is why it would be wrong to make too much of the way in which Mr Fountain's committee last week seems to have uncovered an unhappy tendency towards irregularity in what is, after all, one of the most important—and certainly the most newsy—of the regulatory agencies in the United States. The cyclamate business, after all, has been an unseemly business from the start. To be sure, it will at this stage be something of a comfort for Dr Edwards and his colleagues that there seems to be no substantial case for saying that the FDA has been concealing—or hiding from—evidence that cyclamates are dangerous since the beginning of the sixties. With the worst will in the world, the most that can be said is that it might have been justifiable to take them off the market a year earlier, towards the end of 1968.

Given that the most serious argument against the use of cyclamates is that their efficacy as aids to weight reduction is still in doubt, the most ungainly feature of the pantomime proceedings on October 18 last year is that the banishment of cyclamates was undertaken in such unseemly haste. Can it ever be good government that an important decision affecting not merely the propriety of manufacturers but the peace of mind of a large part of a very large population should be made on a Friday afternoon and made public on the Saturday? Would it not have been much better to have waited for time to plan an announcement that would seem less a response to panic? And would there not have been a case for waiting for more convincing experimental results than those on which the first decision was taken? With this dirty water under the bridge, nobody should be surprised that there should have been attempts to go back on the original decision. That the FDA should have allowed outsiders—even powerful outsiders—to use its machinery for doing this is reprehensible even if, this once, forgivable.

The way in which the FDA should seek to deal with the safety of drugs and food is one of the questions provoked by the inquiry last week, and there is very little doubt that Dr Edwards is right in saying that the first task is to restore a sense of pride to a battered agency. So far, so good. It is also important that some method should be found for assessing more objectively the biological hazards of new chemicals. But the hazards on which attention is now concentrated are not outright poisons but, rather, materials whose effects are necessarily covert and slow. Moreover, in the assessment of the risk of using this or that chemical, there is bound to be a period when experimental evidence first accumulates when it is exceedingly hard to interpret this evidence. This, for practical purposes, is the reason given by the FDA for not acting sooner on cyclamates. It would have been quite proper to wait for even longer. As time goes on, it will be increasingly important to decide whether some material not previously in use should be licensed as safe, which should provide only minor problems. Yet there are bound always to be materials, not necessarily food additives, which are already in use when their safety is questioned. The problem is what to do in the period before such a suspicion can be fully tested. It would be a great boon for the public peace of mind if the FDA were now publicly to resolve to take a measured view of the evidence, circumstantial and otherwise.

What does this imply for the Delaney amendment, the form of words by means of which Congress has sought to put an end to cancer? Dr Edwards last week nailed his colours to the mast of this legislation, but that is hardly the point. The practical question is how the amendment is to be applied. What kind of evidence is to be taken as a proof that some foodstuffs may be carcinogenic? Is there to be a ban the instant that a tumour appears in an experimental animal? What does Congress require for a test of significance in the comparison between a group of experimental animals and the controls? Is a probability of chance occurrence less than 0·5 sufficient to outlaw some previously unsuspected chemical? Or will Congress wait until the evidence justifies a more certain conclusion? By cheering on the Delaney lobby last week without raising the questions which should still have been fresh in his mind about the cyclamate decision bequeathed to him by Dr Herbert Ley, Dr Edwards may find that he has given an uncomfortable number of hostages to fortune.

Another difficulty in the administration of this legislation is the means by which the FDA should combine its judicial and its scientific functions. Mr Fountain's committee may too lightly have ignored last week the value of the research which the FDA carries out, but nobody seems fully to recognize the intellectual difficulty of the judicial function. If there is anything at all to be learned from the unseemly taking of decisions on cyclamates and on the package insert for oral contraceptives, it is that the quasi-judicial proceedings of the FDA should be made more formal. Other regulatory agencies of the Federal Government have several commissioners to share responsibility and it is hard to see why the FDA should not move at least a good distance in that direction by the appointment of an old-fashioned council to solemnize decisions and to share responsibility for them. Without such an instrument, properly constituted by Congress, each successive commissioner will find himself intolerably squeezed between the bureaucracy of HEW and the imitators of Mr Ralph Nader.

The FDA also needs a more rational definition of the function of its scientific work, the origins of which are to be found in the simple days when the acme of vigilance was the identification of unexpected contaminants in ordinary food—insect parts in flour was a perennial favourite. The task, in short, was the enforcement of regulations already in force. The novelty in the past few years has been the way in which the FDA has also assumed some of the public responsibility for seeking out those agents in the environment, natural as well as artificial, which may be suspect. Dr Henry Simmons, the director of the FDA's Bureau of Drugs, put one of the obvious difficulties well when he described last week the way in which turning over every stone raised a host of unexpected problems. The trouble, of course, is that, however hard it tries, the FDA will never be able to do everything that might be tried. Some of its attempts to outdo Mr Nader in the past few months have shown that, with the best will in the world, the FDA's scientific branch will be able only to tackle a small part of what needs to be done if mutagenesis and teratogenesis as well as more tests are to be applied to the ingredients of ordinary life.

But if the FDA cannot be at once judge and detective agency, where should it concentrate ? The most urgent need, of course, is that the FDA should be strongest in the determination of the criteria on which safety and danger are determined. What this implies is that the FDA should be skilled at defining the protocols which must be satisfied by the tests which manufacturers carry out, and that it should be most of all concerned to advance the techniques by means of which these tests can be applied. At the same time, it should be wary of trying to function as a fire-fighter whenever the prospect of some new danger is raised—the danger is that too rapid investigation with inadequate resources may serve only to confuse the issue (as with cyclamates). In the long run, the FDA's best hope is that by the judicious placing of contracts with outside researchers, and by the stimulation of a professional interest in this important work, the FDA can more effectively harness the energies of the scientific world to its important cause. In doing this, however, the FDA would be well advised to lessen its growing dependence on the committees of the National Academy of Sciences—the objective should be a vigorous and open community of active researchers and not a device for investing decisions with prestige.

There remains the most glaring and the least readily acknowledged of all the FDA's shortcomings—its tendency to act independently of what happens elsewhere. In this sense, the United States is well on the way to becoming the largest island in the world. But is there any reason to believe that manufactured chemicals such as 2,4,5-T are different in the United States and Europe ? Is there no means by which the assessment of the hazards of drugs, food additives and other potentially hazardous materials may be carried out internationally ? It is true that arrangements for such activities might seem to be a diminution of the right of Congress to look after the health of United States citizens, but that is not a serious consideration. If Dr Edwards wishes to make a constructive mark on the FDA, he will seek not merely independence from the secretary of HEW but also a much closer working relationship with comparable organizations elsewhere.

A Cure for Cancer Research

THE appointment of a committee to coordinate cancer research in Britain, many years overdue as it is, is one of the most hopeful signs of progress in this inevitably troubled field. The delay in appointing the committee, once the Medical Research Council had decided to set it up more than six months ago, aroused fears that the committee was not intended to play any serious part in cancer research. But now that the members have at last been announced, it seems that the committee should be well able to exert a firm and beneficial management over its field of influence.

The committee, which is to be known as the Coordinating Committee on Cancer Research, is sponsored by the three organizations that fund cancer research in Britain. These are the Medical Research Council (MRC), the Cancer Research Campaign (CRC), which recently dropped the British Empire from its erstwhile title of the British Empire Campaign for Cancer Research, and the Imperial Cancer Research Fund (ICRF).

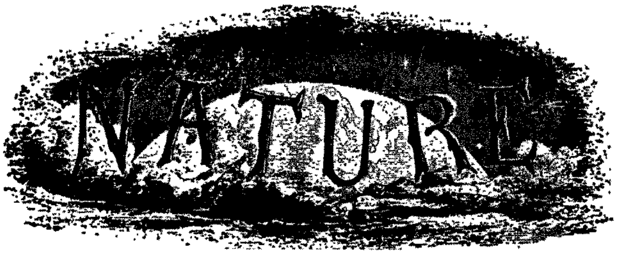
Membership of the committee is restricted to the research directors of the four major British institutes—Dr M. G. P. Stoker of the ICRF, Professor T. Symington of the Institute of Cancer Research, Dr L. G. Lajtha of the Paterson Laboratories, Christie Hospital and Holt Radium Institute, and Dr John Paul of the Beatson Institute for Cancer Research, together with representatives of the three funding agencies, Sir Brian Windeyer for the MRC, Professor T. Crawford for the CRC and Professor E. F. Scowen of the ICRF. The chairman is Sir Max Rosenheim of University College Hospital Medical School.

The chief use of the committee will be as a forum where the directors of research can talk to each other with the keepers of the purse strings listening in. There is much to talk about. For lack of any previous attempt at coordination, it will be a sizable task simply to catalogue who is doing what and why. Then will come the real work of the committee, that of trying to assess the relevance of this work to cancer research, and whether the present distribution of money and manpower is reasonable. In other words, the committee's decisions will affect not only the domestic policies of the four institutes concerned but also the broad issues of national policy such as whether screening of anti-cancer drugs or experimental chemotherapy should be concentrated at a single institute or dispersed among several centres.

Although the three sponsoring bodies have stated that the committee's function will be purely advisory, it would be tragic if their representatives on the committee should fail to ensure that its advice is listened to. Between them the MRC, the CRC and the ICRF dispose of some £4 million a year on cancer research, which accounts for a sizable fraction of Britain's research expenditure and which, because of the breadth of cancer research, has a significant effect on medical and biological research in general. With the appointment of the committee there is at last an opportunity for devising a coherent strategy as to how these funds should be deployed.

The committee is to hold its first meeting early next month and if all goes well it will probably continue to meet at frequent intervals. One of its first decisions will be how far to make public its judgments and it will be a good augury for an innovative future if it elects to depart, even a little, from the standards of secrecy practised by government bodies such as the MRC.

100 Years Ago



LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Corona

Having been informed that my remarks at the meeting of the Royal Astronomical Society, on Friday last, have been interpreted otherwise than I meant, doubtless in consequence of my having spoken without preparation, I beg to repeat what I intended should have been the purport of my statement.

It seems to me beyond reasonable doubt that we have upon all the photographs, whether of long or of short exposure, a representative of *something which is at the sun*, since the contour of the radiance depicted upon all the photographs exhibits minima, in directions closely approximate to the extremities of the sun's axis of rotation. Furthermore, exterior to all this, and apparently masking it in a very great degree to the ordinary observer, is a much wider and more conspicuous radiance of very irregular outline, to which the name *Corona* has been ordinarily applied. The streamers and irregular projections of this latter corona appeared to me to vary in position during the period of totality in August last. They seem, moreover, to have no connection with the positions of the prominences, nor yet with that of the solar axis, and hence I infer that this phenomenon arises from something *which is not at the sun*.

London, June 15 B. A. Gould

Gould, who was born in Boston, is best known for his catalogue of southern hemisphere stars. *From* Nature, **2**, 141, *June* 23, 1870.

OLD WORLD

ELDO

Successful Failure for Europa 1

Once again the Europa 1 rocket of the European Launcher Development Organization has failed to put a 260 kg Italian test satellite into orbit. This was the sad news from Woomera on June 12 after the last test of the rocket before the programme moves to the new launching site in French Guiana. ELDO has now marked up an immaculately complete history of failures stretching back to August 1966, an inauspicious record to lay before the forthcoming European Space Conference at Brussels.

What seems to have happened this time is that the nose fairings which protect the satellite during the flight through the lower atmosphere were not jettisoned, so that the weight of the payload was increased to an unacceptable value. According to the flight plan the fairings should have been released 223 seconds after launch during the firing of the second stage engines, at a height of about 150 km. That this did not occur was apparently due to the premature disconnexion of a connector plug 78 seconds into the flight. The fairings added something like 300 kg to the weight of the payload.

ELDO is used to putting a brave face on things, and this week a spokesman described the flight as "on the whole very satisfactory". It is true that by ELDO standards the firing could have been called a roaring success. For the first time all three stages of the multinational rocket functioned correctly so that the problems which caused the German third stage to explode on the previous two flights seem to have been solved. According to an article in *Le Monde*, it could have been that the autodestruction mechanism in the German stage was being triggered spontaneously by stray potentials. This would have given rise to the sort of rapid increases in pressure in the fuel tanks that were recorded during the previous two flights. Therefore the most important objective of the flight was achieved, and on the face of it the non-release of the nose fairings ought to be easily solved.

Whether this will cut any ice at the European Space Conference remains to be seen. Postponed to July 22–24 because of the British elections, the conference is at ministerial level and is expected to make at least a start on setting the future pattern of European work in space. In the first place it is hoped that the conference will take a further step towards rationalization of the European space effort by combining ELDO with its sister agency, the European Space Research Organization. But behind all discussions about the part that Europe ought to be taking in space is the debate over whether Europe needs the luxury of a launcher of its own, and the past history of ELDO is inevitably colouring the argument.

Had everything worked perfectly, Europa 1 would have orbited an Italian test satellite of 214 kg and an adaptor carrying radio guidance equipment. Other aims of the flight were to carry out communications experiments using equipment supplied by Belgium, Denmark, Italy, Norway and Sweden and installed in the satellite, and to test the operation of the ground stations associated with the ELDO programme. But this was also the last flight of Europa 1. In the ELDO scheme of things the next step is to test the second configuration of the launcher which includes a French perigee motor on top of the German stage. Eventually everyone hopes that this combination will launch the Franco-German communications satellite.

SOVIET UNION

Madness in the Method

from our Soviet Correspondent

THE case of the geneticist Zhores Medvedev, at present held in a Kaluga mental hospital because of his open protests on the "senseless barriers" imposed by the Soviet authorities on academic and scientific freedom (*Nature*, **226**, 887; 1970), is unfortunately not unique even in the recent annals of Soviet science. The use of the psychiatric hospital as an alternative to prison or Siberian exile was first inaugurated under Stalin and has been resorted to on many occasions since. Among the most noteworthy cases of the last few years are the following.

N. I. Samsonov, a geophysicist, who was awarded a Stalin prize for his arctic research, was interned in the Leningrad psychiatric hospital from 1956 to 1964, after writing to the Central Committee of the CPSU criticizing some of Stalin's theoretical propositions.

Yu. V. Levin, a biologist, wrote to the United States embassy in Moscow deploring the Soviet intervention in Czechoslovakia; arrested and sent to Leningrad psychiatric hospital in November 1968, he was discharged after ten days as perfectly sane.

Petr Grigorenko, now most widely known under his military rank of major-general, was for 17 years director of research and later the head of the cybernetics department of Frunze Academy. He was arrested and declared insane in 1969 for his support of the displaced Crimean Tartars.

Vladimir Borison of Leningrad, a philologist, is now in the Leningrad psychiatric hospital; according to one underground source, his doctors say, "He's perfectly normal, of course, but orders are orders".

Perhaps the best known case is that of the mathematical logician, Aleksandr S. Esenin-Volpin, who since 1949 has been confined to a mental hospital on some five separate occasions. Such work as he has been allowed to publish in interludes of freedom shows no very evident sign of mental disturbance. His most recent arrest, on May 5, 1968, evoked a wave of protests, one of which was signed by 99 mathematicians and physicists throughout the Soviet Union (15 of whom later withdrew their signatures). Since this last arrest, Esenin-Volpin has been subjected to heavy police surveillance, and is not allowed to hold any university post. He is working at present in the All-Union Institute of Scientific and Technical Information—a somewhat routine post, much below his intellectual capacity.

Rehabilitation of erstwhile dissidents has been a notable feature of Soviet policy changes, and some scholars and intellectuals have been fortunate enough to be rehabilitated in their own lifetime. It is, perhaps, one of the more ironic aspects of the Medvedev affair that, almost simultaneously with his arrest, an article appeared in *Soviet Statehood and Law* ((5), 1970), which recommends that special provisions for the liability of the officials concerned in the case of such illegal dismissals or transfers should be included either in a special labour act or in the basic principles of the labour law of the Soviet Union and the Union republics.

DOCTORS' PAY

Consultants and Professors

THE British Medical Association has at last decided to exchange the public prestige of the medical profession for the freedom to bargain like a trade union. In many ways this is a sensible decision because the prestige was being eroded anyway, and the astonishment occasioned by the avidity of the BMA's demands will soon be forgotten. But how will the pay awards to doctors affect people in the universities? Doctors are, after all, only applied biologists, and their training is not necessarily more protracted than that of many academic scientists.

One point at which the recommendations may immediately create ill-feeling is that staff in medical schools who hold honorary NHS contracts, and are paid according to the NHS consultants' scale, will receive a 30 per cent salary increase that will create discrepancies in university pay scales. All medical staff who hold NHS contracts would be paid more than senior lecturers in other departments, and the average professor would be paid less than the average consultant in the medical schools. The old consultants' scale stretched from the middle of the scale for senior lecturers to slightly above the average for professors' salaries. The Association of University Teachers is holding its fire until the Prices and Incomes Board has given its verdict on the recommendations made by the Kindersley committee.

The council meeting of the British Medical Association, reported in last week's *British Medical Journal*, is an excellent example of a learned profession standing on its badly dented dignity. "Our sense of justice has been violated," declared the chairman, Dr Ronald Gibson, and "it is a national disgrace that a noble and dedicated profession should be manhandled and insulted in this way". It is obvious from the report of the meeting that the BMA was never in doubt about the justification for taking industrial action over the reference of half the Kindersley recommendation to the Prices and Incomes Board, and the real question was how far out on a limb doctors could reasonably go. Amidst

Table 1. UNIVERSITY SALARIES AND KINDERSLEY RECOMMENDATIONS FOR DOCTORS' SALARIES

University salaries:	
Assistant lecturers and lecturers	£1,352 to £3,097
Senior lecturers and readers	A range of scales with maximum of £3,900
Professors	Minimum £4,019. The average at any institution not to exceed £5,096
Kindersley recommendations for doctors' salaries:	
House officer	£1,626 to £1,884
Senior house officer	£2,040 to £2,328
Registrar	£2,328 to £2,886
Senior registrar	£2,760 to £3,588
Consultant	£4,512 to £6,855

(The article in *Nature*, **226**, 993; 1970, should have made clear that the figures quoted for doctors' salaries represented maximum scales.)

the high flown oratory which the meeting produced, there was a clear call for resignation as a matter of principle. Many doctors present at the meeting thought that the profession would regard the decision to stop signing medical certificates and to refuse to participate in NHS committees as not going far enough, and Mr J. Elkington, chairman of the BMA's Hospital Junior Staffs Group Council, declared that resignation only meant resignation from the health service, and that doctors would go on looking after patients even if they worked for nothing and even if they starved. It will be interesting to see whether the referendum being conducted by the BMA will bear out the council's estimate of the wrath of the medical profession. Last weekend, the BMA sent about 50,000 forms to doctors, asking whether they would resign from the health service if the review body is not reinstated.

If the level of support for the BMA's recommendation that doctors should refuse to sign sickness certificates is any yardstick, then the council might be in for a shock. To be sure, the BMA claims that its sanctions are enjoying 100 per cent support in some areas, but the Department of Health and Social Security puts the figure at more like 75 per cent, and it seems that several doctors who originally refused to sign certificates have since changed their minds. There is also a clear call from the *Lancet* that the BMA should moderate its temper, and that "thoughts of organized resignation from the health service be banished".

What, then, are the chances of the doctors' militancy getting out of hand ? One factor is that the effect of industrial action will be much less after the election than it was in the middle of the election campaign. In any case, there seems to be a substantial body of opinion even inside the medical profession that doctors are being greedy in sticking out for the full 30 per cent increase. As one consultant said in a letter to *The Guardian*, "I have been amazed at the irresponsible recommendations of the Kindersley committee: well might they resign."

FISHERIES

Sanity on Salmon

Limitations have at last been imposed on salmon fishing in the Greenland area, and in comparison with the restrictions agreed last month for the north-east Atlantic they are surprisingly strict. The prolonged international wrangle about alleged overfishing by Scandinavian drifters was resolved in Newfoundland this month at the annual meeting of the International Commission for North-West Atlantic Fisheries (ICNAF), which decided that each member country should prevent either the tonnage of its salmon fleet or its annual catch in the north-west Atlantic from exceeding the 1969 size. This restriction covers all salmon fishing outside the three-mile limit around the coast of Greenland.

Because ICNAF cannot, according to its constitution, simply impose a maximum tonnage on a national fleet, the individual countries have been left with a choice, but the important point is that limits of one kind or another have been agreed. Several countries, including Britain, were dissatisfied when the counterpart body of ICNAF, the North-East Atlantic Fisheries Commission (NEAFCO), decided last month to restrict salmon fishing on the European side of the Atlantic to an eight-week season each year but not to stop the fleets from expanding (see *Nature*, **226**, 678; 1970). The difficulty then was that any stronger proposal would have been outvoted by Denmark, Sweden and West Germany, and the group of countries, led by Britain and Canada, which had wanted a complete ban to protect their own stocks of salmon, had to be content with rather less than half a loaf.

The restrictions which were eventually agreed upon at the ICNAF meeting were in part the outcome of discussions between English and Danish representatives in the period since the NEAFCO meeting. In the final vote, the Danes, Swedes and West Germans came out in favour of keeping the catches down, and also approved of restrictions on the size of nets that can be used and on the length of the fishing season. Salmon are now to be fished only from August to November; this makes little difference to the principal fishery off Greenland, because the fish are not there at any other time of the year, but will stop the industry from making further inroads into the Davis Strait between Greenland and Canada, where salmon are around for somewhat longer.

Britain is, on the whole, happy with the decision, for in spite of the lack of clear evidence so far, it had been feared that British stocks of salmon might fall if the exploitation of the salmon's Atlantic breeding grounds continue to grow without check. The ideal remedy, that of banning the fishing of salmon on the high seas altogether, would never have been agreed to by the ICNAF meeting.

CONSERVATION

No More Blackbird Pie

Small birds will soon be able to fly fearlessly across the borders of Italy, for the Italian Minister of Agriculture, Mr Lorenzo Natali, intends to introduce a new law to forbid bird netting, a form of hunting that can account for the death of some 10 million migrant birds each year.

This decision, announced by the Italian delegation to the Council of Europe, is surprising because it was only in January this year that the Italian government gave way to one of its most powerful lobbies—there are about 1,800,000 hunters in Italy—and passed a Bill permitting the netting of small birds, thereby negating a Bill passed some three years earlier which had stopped netting in most of its aspects. The government argued that the new Bill was necessary to enable birds to be captured for scientific research—a claim strenuously denied by the Italian National Research Council—but it was clear that most of the netted birds would end up not in a laboratory but in pies or pâtés.

The Bill evoked an immediate outcry all over Europe; it seemed especially tactless that the Bill should be passed in the first month of European Conservation Year. Conservation societies voiced their complete opposition and many sent protests to the Italian government. The International Council for Bird Preservation, for example, urged people to write to Italian embassies and tourist boards to make their views known and the response to this plea was apparently world-wide. In Italy there was a strong body of opinion opposed to the Bill, and Dr P. L. Florio, senior trustee of the Italian National Appeal of the World Wildlife Fund, had collected half a million signatures on a petition which was to be presented to the government in the near future. In March the World Wildlife Fund sent a request to the Italian Foreign Ministry and the Ministry of Agriculture asking for the total abolition of bird netting in Italy.

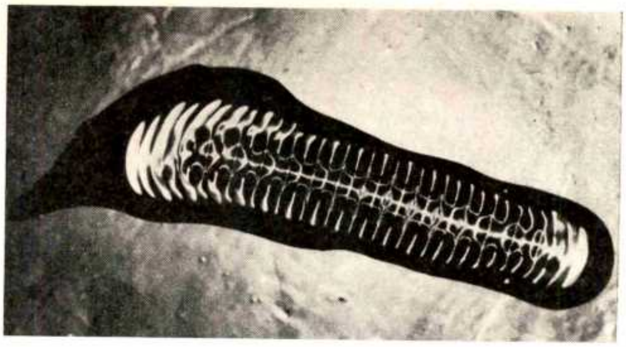
It seems that all this pressure has borne fruit and the Council of Europe now hopes that other countries, such as France, Greece, Spain and Portugal, will soon follow Italy's example. It is hard to know how widespread netting is outside Italy, but statements to the council from national delegations and from the International Hunting Council have revealed a thriving trade in netted birds between several member countries, and the council believes that coordinated legislation is needed in all parts of Europe against netting and the importing and exporting of netted birds.

EXHIBITIONS

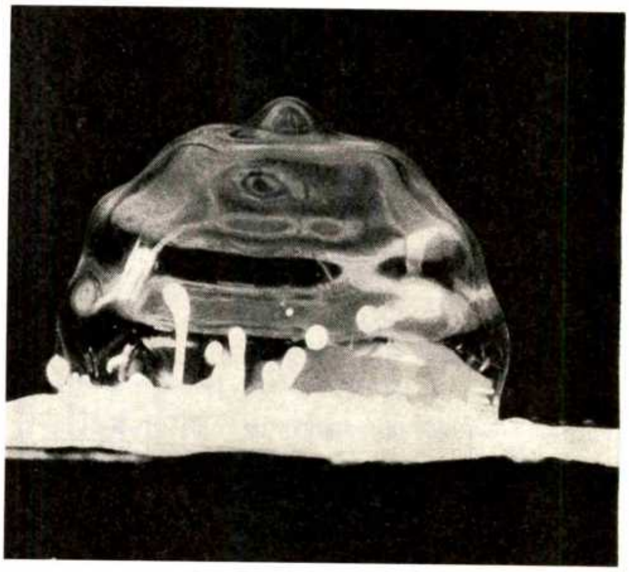
Patterns of Sound

A REMARKABLE exhibition of matter tortured by sound is on display until July 22 at the Institute of Contemporary Arts in London. The exhibition is the work of Dr Hans Jenny, a Swiss physician, who has improved on Chladni's contribution to science by extending the range of forms and shapes that can be extracted from matter by vibrations. Whereas Chladni to get his famous figures merely sawed with a violin bow on a sand-strewn metal plate, Dr Jenny has applied crystal oscillators to glycerine, mercury, lycopodium powder, turpentine and the many other substances that are grist to his mill.

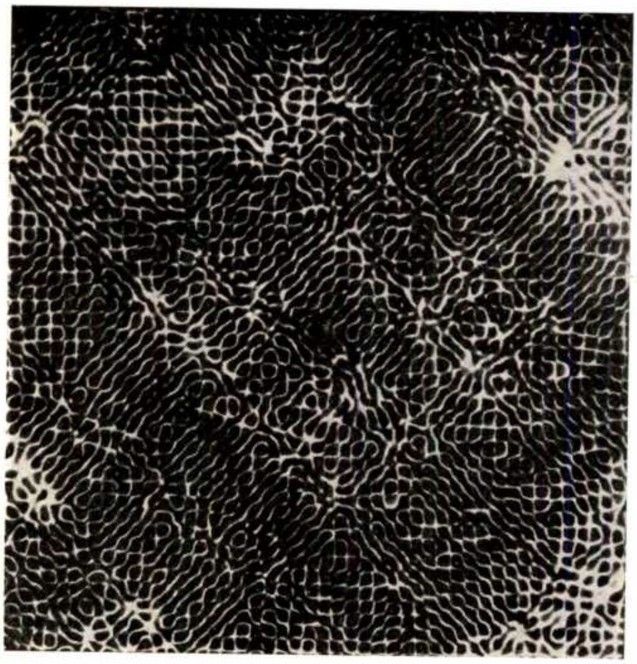
The results, recorded in the form of photographs and a non-stop film show, are a spectacular travelogue to a through-the-mirror land where ordinary physical laws seem to be held in abeyance. Who would believe that a soap bubble could shape itself into a dodecahedron and grow a stalk, looking to all the world like a bacteriophage ? Or that water droplets could move sideways in squares ? Or a blob of glycerine metamorphose into a vertebral column with 35 segments ? Jenny's work shows how inanimate matter charged with vibrational energy can assume shapes of unexpected subtlety and vitality. Anyone who is tired of the humdrum behaviour of matter in the laboratory should visit the ICA exhibition to see the elegant but other-world sculptures that can be conjured out of paste, powder and iron filings.



Glycerine vibrated at 30 Hz (length of figure is 4 cm).



Soap bubble vibrated at 110 Hz forming a pulsating polyhedron (spikes of liquid soap in foreground).



Chladni figure formed by quartz sand vibrated on a steel plate at 16,800 Hz.

UNIVERSITIES

Imperial Quart in Pint Pot

THE Herculean task of reforming the administrative structure of London University with its three-quarters of a million students and eleven federated colleges has been allotted to an independent committee under the chairmanship of Lord Murray of Newhaven, the director of the Leverhulme Trust Fund. Following the recommendations made by the university senate last January (see *Nature*, **225**, 492; 1970) the chief aim of the committee will be to look into the future of London University as a federal institution, concentrating particularly on such questions as the function of the senate, the relation between individual colleges and the university, and student participation.

The committee has been appointed jointly by London University and the University Grants Committee (UGC) and the hope is that it will report within two to three years. Five of the ten members are from outside the university and include Professor W. M. Cooper and Professor F. S. Dainton, the Vice-Chancellors of Manchester and Nottingham Universities respectively.

One of the most immediate problems before the committee is what to do about the 35,000 external degree students who are examined but not taught by the university. Despite the establishment of the Council for National Academic Awards (CNAA) in 1962, the number of external students has been growing rapidly and the senate has warned that if the number of school leavers increases as fast as the Department of Education and Science predicts, the present London University external degree system will be unable to cope.

Some of the hardest in-fighting may be done over the distribution of finances within the university. The University Court is responsible for dividing out the block grant from the UGC between the individual colleges although for the present, at least, Imperial College and Chelsea College have funds allotted specially for them by the UGC. But rumours of secession and unilateral declarations of independence have long been in the air, and up and down Prince Consort Road and in the shadows of the Albert Hall there can be heard faint mutterings that Imperial College would perhaps do better to be known to the world as the University of Kensington. This, no doubt, is one of the matters that will exercise the attention of Lord Murray's committee.

ATMOSPHERE

Whitewashing Coal

The development of fluidized bed processes for burning coal more economically and less poisonously, now under way in the laboratories of the National Coal Board, has attracted backing worth £125,000 from the US National Air Pollution Control Administration. According to an agreement signed this month by Lord Robens, chairman of the NCB, and Mr John T. Middleton, commissioner of NAPCA, the two organizations will jointly finance a £0·25 million programme which includes further research into the capacity of fluidized beds for retaining sulphur and oxides of nitrogen in the ash instead of liberating them into the atmosphere. This agreement follows a decision in principle to cooperate over the process, which was taken last year.

The basis of the process is that the air required for combustion is blown through a bed of coal particles, and because the solid mass then behaves as a liquid, boiler tubes can be immersed in the bed. As a result, heat transfer improves and the boiler need not be as voluminous as usual—a 660 MW boiler for a power station, for example, might be only about 50 feet high, compared with more than 200 feet for the most recent conventional designs, and if the coal is fluidized with air under pressure the size can be shrunk further. If limestone is added to the coal, most of the sulphur can be trapped in the bed, together with a fair proportion of the oxides of nitrogen.

So far plans for large fluidized bed boilers are confined to design studies, although the NCB is now thinking of installing a pilot unit at a power station in Grimethorpe. A small prototype shell boiler, giving 8,000 pounds/h of steam, has been running for more than a year at the Coal Research Establishment near Cheltenham, and this is providing the data on which larger designs are to be based.

DESALINATION

Freezing out Brine

Plans for a large experimental desalination plant to be built at Ipswich are being considered by the government, Lord Kennet, Parliamentary Secretary at the Ministry of Housing and Local Government, said in London last week. The proposals, put forward by the Atomic Energy Authority and the Water Resources Board, are for a plant to produce a million gallons of water a day using a new process in which the salt is removed by refrigeration.

The traditional means of desalinating water is by flash distillation, in which fresh water is obtained by repeated condensation. This method has been adopted by several countries which have embarked on desalination programmes, but its economic viability has often been questioned. The power consumed by the process is large, and the attractions of linking such an installation directly to a nuclear power plant have so far proved illusory. As pointed out by the head of the International Atomic Energy Agency at the recent conference on desalination in Madrid, only the advent of fast reactors will bring about a significant change in the economics of desalination by this means. But operational fast reactors are still a decade or so away.

For a country such as Britain, the relatively low temperature of the neighbouring seas is considered an additional factor in favour of experimenting with the refrigeration process. Less power is consumed in this process, in which impurities are removed in the form of a brine slurry by the addition of a hydrocarbon freezing agent, and although no large scale plant has yet been built, test installations built by Simon Engineering in Stockport—producing 10,000 gallons a day—and by the Atomic Energy Research Establishment, Harwell, have produced promising results.

When the desalination programme started at Harwell in 1965 the emphasis was chiefly on flash distillation. Over the first three years the government spent £1·3 million on this programme, and although there are more than 100 distillation plants for desalination in industry it became steadily clearer that for domestic supplies the refrigeration process was likely to prove more economic. Work on the desalination programme is also being carried out at the AEA establishments at Risley and Winfrith.

Although countries such as the United States and Israel are also interested in the refrigeration process, flash distillation is still the most common technique. The French company SIDEM is at present enlarging the desalination plant at Le Havre, which turns out a million gallons a day by distillation, and it is believed that for a country such as France with frequent shortages of water there will have to be increasing reliance on desalination plants in future.

NEW WORLD

Food and Drug Maladministration

THE Food and Drug Administration, which has been struggling since last December to find a secure basis for continued survival, fell flat on its face again last week at the public inquiry before Representative L. H. Fountain's subcommittee of the House Committee on Government Operations. Although the new Commissioner, Dr Charles Edwards, began his evidence by deliberately washing his hands of a good deal of the past, at the end of a gruelling two days he was reduced to silence by the chairman's declaration that the "integrity and importance" of the law on which the FDA's operations are founded is being "eroded" by the FDA's interpretation of it in the past few months. For a time, at least, it began to seem as if many of the charges levelled against the FDA by Mr Ralph Nader and his colleagues (see *Nature*, April 18, page 205) may be correct. And although Dr Edwards's colleagues and associates insist that he is doing a splendid job, it is plain that there is a long way to go before he can put his house in order.

The most serious bone of contention last week was the way in which arrangements have been made to allow soft drinks and other commodities containing cyclamates to be reintroduced to the market in the United States by classifying them not as foods but as non-prescription drugs. The Fountain committee and the FDA are united in believing that cyclamates are a hazard to health, but Dr Edwards and his staff seem to have been at once inconsistent and rather less than their own masters in devising the arrangements by which many products containing cyclamates will be kept on the shelves of many supermarkets when the supposed ban on their sale becomes effective by the simple device of relabelling them as drugs. Mr Fountain said that the episode "gives the impression of being a subterfuge to keep cyclamates in circulation", and that his only comfort was the FDA's promise to look at the position within a year to make sure that the availability of cyclamates would not be abused.

The day-long row about cyclamates was evidently regarded by the committee not merely as an issue in its own right but as a test of Dr Edwards's intentions to make the FDA into a vigorous and independent organization, and everybody agrees that he has a Herculean task on his hands. Indeed, the inquiry opened with Dr Edwards's own declaration that when he was appointed to the FDA on December 15 last year, the scientific competence of the FDA was "poorly marshalled", with a "clear imbalance between scientific and regulatory responsibilities. The decision making environment was disorderly. Professional talent was stifled, poorly directed and unmotivated. Planning was shockingly myopic".

In the reform of the FDA, Dr Edwards said that he plans to increase the degree to which it relies on consultation from outside, and he said that the National Academy of Sciences–National Research Council has already agreed to do even more work than at present on the revision of the list of food additives permitted for use (the GRAS list) and on its continuing study of drug efficacy. To review the balance of the FDA's internal operations, an independent scientific committee has been established, while permanent advisory councils will be set up to advise the three bureaux (Food, Drugs and Pesticides). Evidently in an attempt to anticipate the sudden crises which have afflicted his predecessors, Dr Edwards has set up what he calls a "critical reporting procedure" by means of which professional people within the organization can bring potential difficulties to his attention.

Ralph Nader.

The independence of the FDA was one of the preoccupations of the subcommittee. Who is the boss, the Commissioner of the FDA or the Secretary of Health, Education and Welfare ? One of the inevitable difficulties is that the FDA differs from most regulatory agencies in being responsible to a cabinet officer and not to Congress. Dr Edwards said last week that he would not have taken his new job if he had not been assured of having sole responsibility for administering the law on food, drugs and cosmetics, but he was quickly tripped up by a quotation from a letter on the FDA files in which one member of the staff, anticipating problems likely to arise during a meeting on cyclamates with industrial representatives, suggested that "it is important that industry should do most of the talking" and that the officials of the FDA should insist that they were merely advisers to the Secretary of HEW. The truth, it seems, is that Dr Edwards agreed before he joined that cyclamates were a special case and that higher authorities would make the important decisions. Dr Edwards also volunteered that he has an agreement with the Secretary's office, chiefly in the persons of Dr J. Steinfield, the Surgeon General, and Dr Roger O. Egeberg, Assistant Secretary for Health and Scientific Affairs, to provide advance warning of FDA decisions likely to cause trouble, but he also argued that the right of access to the Secretary which had been established gave his agency enough strength to be able to "move in the direction" of what one committee member called maximum freedom.

Within the agency, Dr Edwards said that his policy was to "push down" the level of decision making, and that formal studies were now being made of the procedures which would be necessary to allow decentralization of procedures such as the rejection of applications from manufacturers for approval for food additives and drugs. Dr Edwards was frank about the extent to which staffing problems hamper this process, and said that "because of poor management within the agency, people have been badly used". Dr Edwards also agreed with a suggestion by one of the committee that public service regulations make it hard to deploy people in a way that is likely to make the best use of them—"This has been a problem in the past five months. It does slow things down. The regulations do make people too secure. The contrast with private industry is striking."

But may not the FDA be hamstrung by too little money ? Dr Edwards was eloquent on the subject—"we are one of the badly funded agencies in the federal government and you can't regulate an industry with a turnover of more than $20,000 million on a budget of between $80 and $90 million a year". In reply to several questions, Dr Edwards thought that the discussions now under way with the Bureau of the Budget would mean that the FDA would have to drop some of its plans for communicating more effectively with the medical profession, but he did promise that priority would be given to the revision of the GRAS list on which work has already begun and the strengthening of the FDA's work in carcinogenesis and teratogenic chemicals.

The plea for more money did not instantly melt the heart of the subcommittee's chairman, who asked that the FDA should pay more attention to the enforcement of the law, if necessary at the expense of its scientific work. He pointed out that between 1945 and 1968, the FDA budget had grown from $4 million to $66 million and its payroll from 850 to 5,100 people. In the same interval, however, the number of occasions on which FDA inspectors had seized consignments of food had declined from 2,504 to 384 and drugs failing to satisfy the regulations had been seized on 594 occasions in 1945 but on only ten in 1968. Mr Fountain held that these statistics were not so much a proof of the FDA's success—one interpretation of them—but of a turning away from the strictly regulatory aspects of its work. "The reason for the FDA's decline may be attributed in part to the morale of FDA personnel", itself a product of frequent changes of leadership, frequent reorganization, physical moves from one building to another, programmes begun and not completed, fear of displacement because of frequent changes and uncertainty as to FDA enforcement programmes and policies. Dr Edwards agreed that "the morale of the agency has been low and is still low, but we're dedicated to making it a topflight agency".

Much of the discussion at the inquiry last week concerned the way in which the FDA has set about trying to make sure that all purchasers of contraceptive pills are warned of the potential danger. This has been a running sore ever since last March, when the FDA's proposal for a statement of the dangers running to 600 words found its way into several newspapers in the United States. According to Dr Edwards, the intention then was to make sure not merely that women using the pill were aware that these materials are potentially hazardous but also to provide them with statements of the possible side effects, contraindications to the use of contraceptive pills, a list of signs of possible trouble, advice about the use of contraceptive pills in several circumstances, as for example during lactation, and a description of the long term experiments being carried out to test for the occurrence of cancer in laboratory animals. By Dr Edwards's account, the appearance of this long statement led to such a degree of protest from medical bodies and pharmaceutical manufacturers that he became convinced that it was not for the FDA to play doctor. The result, announced last week, is that in future (or after the 90 days during which interested parties may object) all packets of oral contraceptives will contain a simple statement advising women not to take the drug without continued medical supervision and advising them that a fuller statement, prepared by the manufacturer, will be available from physicians. He promised that the FDA would be vigilant in making sure that the new booklets were an adequate primer in the theory and practice of oral contraception.

Here again, so the inquiry last week suggested, the FDA's policy tends to be fuzzy at the edges. One question, for example, is whether it is possible to assume that all women using oral contraceptives, either now or in the future, will have access to medical supervision or, for that matter, whether they will be able to read English. At one point, Dr Edwards found himself admitting that large numbers of women obtained supplies of oral contraceptives by sharing a common prescription, although he considered that out and out illegal traffic in oral contraceptives is probably negligible. But why, then, back down from the policy that "the public has a right to know about the benefits and the side effects", and why not consult the medical advisory committee on the form of words now to be inserted in packages of oral contraceptives ? Plainly the FDA has bowed to the wind blowing from outside as well as within the Department of Health, Education and Welfare.

In the past few months, the FDA has also been plagued by criticisms of having suppressed or even perverted the results of scientific studies carried out in its own laboratories. On this point, both the FDA and the subcommittee agreed that there is no substantial case to answer. The chief source of these accusations is Dr Howard Richardson, a pathologist at

FDA, who made public earlier this year charges that some of the early studies on the potential damage done by cyclamates may have been falsified. According to Dr Edwards, there has since been a thorough study of Dr Richardson's charges, from which it has emerged that one of the cases in which information is alleged to have been suppressed consisted of a study in 1950 in which cyclamates were fed to a strain of rats with a congenitally high incidence of lymphosarcoma. According to Dr Edwards, both the experimental rats and the control group emerged with the same incidence of tumours, for which reason the pathologists concerned did not consider the result significant. Mr Fountain announced that his own staff, following up the same allegation, had discovered that the pathologists whose scientific studies were alleged by Dr Richardson to have been falsified or suppressed had since dissociated themselves from the charges.

But where does the FDA stand on the Delaney amendment ? How vigorously, in other words, is it prepared to enforce that piece of the law which holds that any substance fed to any experimental animal by mouth and which is afterwards found to cause cancer should be prohibited from use in human foodstuffs ? This has been an important question in the past few weeks, if only because the Department of Health, Education and Welfare has let it be known that it is impatient with the rigours of the Delaney amendment, the grounds on which it was necessary last year to ban cyclamates (see *Nature*, **224**, 398; 1969). Dr Edwards said last week, "I think there are some improvements to be made, but until I have had more time for study" the ban must stay. Of the discussions being held within the Department of Health, Education and Welfare about the Delaney amendment, he said that he believed both Dr Steinfield and Dr Egeberg were anxious to "strengthen" the Delaney amendment and not to weaken it, by which he meant, if a prolonged and uncomfortable period of questioning is to be taken at its face value, that the Department of Health, Education and Welfare is about to propose that mutagenicity and teratogenicity will be added to the present requirements that foodstuffs should lack carcinogenicity.

The saga of the cyclamates occupied the whole of the committee's time one day last week. On the whole, the FDA was able convincingly to demonstrate that there was no reason for removing cyclamates from the GRAS list until the late sixties. Admitting that the GRAS list should include only substances about which there was no reasonable doubt, however, Dr Edwards found himself listening to a long recitation from the chairman of occasions dating back to October 30, 1967, on which apparently responsible bodies, including the Food Additives Committee of the National Research Council, had raised questions about the safety of cyclamates. Dr Virgil Wodicka, director of the Bureau of Foods, Pesticides and Product Safety, pointed out that the interpretation of preliminary results is necessarily difficult and Mr William Goodrich, Assistant General Counsel to the FDA, pointed out that much of the early research was supported by the Sugar Foundation and that "their lawyers bombarded me with all kinds of arguments". According to Mr Goodrich, the proposal to remove cyclamates from the GRAS list first arose in April 1969. Dr Edwards considered that it should have been possible to prohibit their general use before October 15, 1969, although he "wouldn't say quite when".

The tale of precisely how the ban was announced, recited by Mr Goodrich, sounded last week a sufficient explanation of the confusion which followed. The results of the feeding experiments carried out by the Abbott Laboratories in which mixtures of cyclamate and saccharin were fed to rats were said to have reached the FDA on a Monday morning and were considered both by the Surgeon General and by officials of the National Cancer Institute. A meeting of an advisory committee arranged for the Thursday of that week was provided not merely with a presentation by the Abbott Laboratories but also with an analysis of the microscopic slides of supposed bladder cancer in the experimental rats. In the course of 36 hours, the advisory committee was apparently convinced that cyclamates should be removed from the GRAS list and the decision to do so was approved by the Secretary of the Department of Health, Education and Welfare, Mr Robert Finch, on the Friday afternoon and was made public at a press conference the following day.

What has followed since seems to be the blackest mark in the FDA's new record. According to evidence at the inquiry last week, principally that of Mr Goodrich, an *ad hoc* committee called by Dr Egeberg recommended cyclamates should be made available as non-prescription drugs for use by diabetics and obese people. (Insulin is one of the non-prescription drugs on sale in the United States.) Mr Goodrich said that he was "called upon" to see whether this decision could be implemented legally and that he decided there would be no objection to making materials containing cyclamates available. The question with which the committee eventually defeated the FDA was whether it is possible to exempt a substance from the provisions of the law about food safety simply by labelling it a drug—one of the documents in the case is one of the FDA's own regulations which lays down that an application for the approval of a new drug (among which the cyclamates are now numbered) must also be considered as an application for the approval of a food additive if the substance concerned materially changes the characteristics of the food. But there are also doubts about the fairness of marketing foodstuffs including cyclamates in circumstances in which they will be placed on supermarket shelves more or less in their old familiar places and freely available to all purchasers. Given the way in which it has also been arranged that applications for the new licences to market cyclamates will be processed not by the FDA in Washington but by the regional offices, which will have power merely to approve the cautionary label to appear on containers, it is no wonder that Mr Fountain complained that it was hard to understand the rationale of the FDA's procedures. The explanation is probably that provided by Dr John Jennings, Associate Commissioner for Medical Affairs, who explained that applications for registering cyclamate products as new drugs "did not require scientific data about efficacy or safety, that question having been resolved for better or worse". Evidently this was an occasion on which the lawyers and not the scientists made policy. Dr Edwards's success in the months ahead will no doubt depend on the extent to which he can assert the right of technical people to make technical judgments.

PERUVIAN EARTHQUAKE

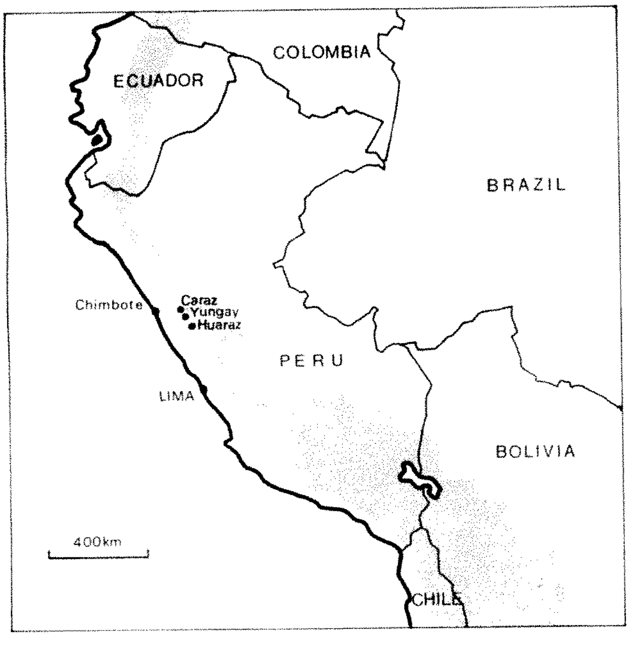
Price of New Sea Floor

from our Geophysics Correspondent

THE earthquake in Peru in June may well have claimed more than 50,000 victims and the number could be much greater. The earthquake is thus comparable with the most catastrophic known—the Lisbon earthquake of 1775, which claimed about 50,000 lives, and the Kwanto earthquake of 1923, which killed 100,000. The epicentral region was about 300 miles north of Lima and the damage wrecked four cities, one, Chimbote, on the coast and three, Caraz, Yungay and Huaraz, about 75 miles inland. Several other villages in the same canyon as these three cities were also wrecked. Two mountain ranges, the Negra and Blanco ranges, rise up on each side of the canyon. The access roads have been destroyed and reaching the region by air has been made impossible by the flooding of the only airport in the region at Caraz. It seems likely that much of the damage was done by the rupturing of the walls of a dammed lake, Lake Llanganuco.

The magnitude of the event was recorded as 7·75 on the Richter scale, a figure which can only be an approximation because such a huge disturbance drives seismometers off scale practically all over the world. The figure is somewhat smaller than that for the San Francisco earthquake of 1906 and that in Alaska of 1964, but the damage, of course, is determined much more closely by the relative positions of epicentre and the centres of population. Thus an earthquake of comparable magnitude in the Aleutian islands in 1965 drew no attention at all because of its remoteness.

The cause of the circum-Pacific earthquakes is now fairly well understood. New sea floor is created along the East Pacific Rise, a mid-ocean ridge running from south of Australia to Mexico. More, in fact, than just sea floor appears to be created—the outer 50 to 100 km of the Earth, called the lithosphere or plate, is formed by solidification of molten regions along the rise and lateral transport away from the region of creation of new plate. The sources of energy for this process, while almost certainly convective, have not yielded to any simple approach to the problem. The East Pacific plate (in this case) moves eastwards at about 5 cm/yr until it encounters the leading edge of western South America, which is part of the South Atlantic plate. Just offshore, the plate is bent through 45° (the source of much seismic activity), underrides the Andes (this is probably the most destructive region) and continues to show sporadic activity down to several hundred kilometres along this dipping plane. The deep ocean trench just off the South American coast is undoubtedly a surface manifestation of the start of the downward plunge.



The sliding of one plate past another is a potentially dangerous process. The San Andreas fault in California is an example of such sliding along a vertical fault plane. The sliding occurs along the 45° dipping plane under South America and in many other regions round the Pacific. It seems that in many regions this relative motion of a few centimetres a year is accommodated by some sort of lubrication (ground water has been suggested) or by repeated small earthquakes, but certain regions (well known in California but practically unmapped elsewhere) stick for periods of tens of years while the stresses build up. Strain energy can be stored in the vicinity of these locked faults until the relative displacements between two points far from the fault reaches ten metres, but then stresses exceed the elastic limit and a catastrophic breakdown occurs along the fault plane with the surrounding region jumping to its new unstrained position. A large number of smaller aftershocks usually occur as readjustment continues, and in Peru at least 100 aftershocks have been reported. It is likely that the width of the region of accumulated stress in this case was about 100 km parallel to the coast line and the length of the fault down the dip was between 20 and 50 km. The Chile earthquake of 1960, somewhat larger, appeared to have a width of about 1,000 km.

Does a huge earthquake in Peru cause other earthquakes, or does it release strain and reduce the chances of an earthquake elsewhere? As far as anyone can tell, the answer to both these questions is no. There has been some speculation that one earthquake may trigger another, but the evidence is slight beyond the region of local strain readjustment (perhaps 1,000 km).

Could such an event have been predicted or even controlled? This is a topic which is receiving growing attention in the United States where the problem in California is more severe than many are prepared to acknowledge. Research around the San Andreas fault is beginning to pinpoint the regions of large strain accumulation where the size of the future earthquake grows with every year that it is postponed. But although it is known that some regions have large amounts of potential energy stored in them, premonitory signs are very difficult to come by. There is some evidence of dramatic strain changes before earthquakes and, rather surprisingly, of very small magnetic fluctuations, but the science is a long way from being sufficiently well established to deliver credible warnings. On the control side, some very interesting developments are occurring with fluid injection experiments. These are in an early stage but seem to bear promise that regular lubrication of a fault would encourage more frequent small slippages. All this, of course, is cold comfort for the residents of South America and Japan where the faults are rarely accessible and there is certainly no money for even pilot experiments in fault lubrication.

NEWS AND VIEWS

Antigens Unmasked

EVEN the most imperceptive observer must have realized that research into the structure, composition and function of cell membranes is very much in vogue. Numerous molecular biologists, bored with *E. coli* and its viruses, can be found toying with red blood cells, retina, synapses and the like, all of them materials which only two or three years ago were strictly left to the physiologists. At the same time tumour virologists are beginning to pay increasing attention to the changes in the cell surface that accompany the transformation of cells by oncogenic viruses. It is now clear that transformation by the small DNA viruses SV40 and polyoma, the genomes of which specify probably less than ten proteins, results in surprisingly complex changes in the surface antigens of the transformed cells.

One of the more interesting ideas that has emerged to account for the complexity of these changes is that SV40 and polyoma viruses somehow induce the specific uncovering of antigenic components which are present in the membranes of untransformed cells but are masked and therefore not accessible to the immune system. Häyry and Defendi (*Virology*, **41**, 22; 1970), for example, report the detection, by mixed haemagglutination and indirect immunofluorescence, of a specific surface (S) antigen on SV40 transformed cells. This antigen is present neither on the untransformed cells nor on cells of the same lines transformed by polyoma virus. To that extent the S antigen is specific to SV40 transformation, but it is not apparently a product of an SV40 gene. Mild short term digestion of untransformed or polyoma transformed cells with trypsin or chymotrypsin, but not papain, ficin or neuraminidase, exposes the S antigen characteristic of SV40 transformation.

The S antigen does not seem to be related to other changes in the cell surface which accompany transformation. It does not, for example, cross react with the Forsmann antigen, the amount of which is known to increase after transformation with polyoma or SV40 viruses. It is not apparently related to the sites which bind wheat germ lipase agglutinin and it is not hematoside, which is present in a masked form on the surfaces of untransformed cells and in an incomplete form on transformed cells.

Ben-Bassat, Inbar and Sachs (*Virology*, **40**, 854; 1970) have followed the appearance of another change in the surface of cells transformed with SV40. Last year Sachs's group reported that 85 per cent of the sites capable of binding concanavalin A are cryptic on untransformed cells but become exposed after transformation. They now claim that cells must divide at least once after SV40 infection and reach a density of 10^5 cells per cm^2 before this exposure of cryptic sites occurs. After infection with SV40 many of the cells which bind concanavalin A are abortively rather than stably transformed. As these abortively transformed cells continue to divide they lose the transformed cell phenotype and the binding sites revert to the cryptic state. If, however, they are maintained in conditions which inhibit cell division they retain the capacity to bind concanavalin. The exposure of these binding sites is a phenotypic characteristic of all transformation by SV40 but a genotypic character only of stably transformed cells. Obviously, just how a small oncogenic viral genome brings about such striking changes in the surface of its host will be one of the chief preoccupations of tumour virologists in the next few years.

PROTEINS

Assorted Assembly

from our Molecular Biology Correspondent

SELF-ASSEMBLY is still probably one of the most potent totems to let slip in one's grant applications, and T4 phage is a favoured example. The phage head is a system of considerable complexity, and the interdependence of its several protein components has been demonstrated by the study of mutants with a malfunction in one or other gene. The latest chapter in this long story, unfolded over the years largely by Kellenberger and his associates, is to be found in an article by Yanagida *et al.* (*J. Mol. Biol.*, **50**, 35; 1970). Seven genes have been implicated in defining the phage head structure, and the function, or at least the consequences of malfunction, of five of them has been determined. One gene, designated 23, is responsible for the predominant subunit protein, whereas others determine the elongation and shape of the head, and one seems to prevent a non-specific aggregation of the 23-protein. Among other deviant forms that have been recognized, an error in gene 22 causes the formation of long tubes, or "polyheads".

Yanagida *et al.* have studied the structure of the tubes by optical diffraction of electron microscope images. Earlier discrepancies are resolved by the demonstration that the tubes consist for the most part of several concentric layers, but that these tend to separate on lysing the cells, so that electron micrographs give the impression of particles of variable diameter. In the intact structures one sees always an inner shell of some 290 Å inside diameter. Successive layers number up to seven or more in some particles, and their separation is about 70 Å. The tubes bear a helical lattice pattern of variable pitch and a right-handed screw-sense.

Evidence has now appeared, however, of some unsuspected depths in the self-assembly process. For example, Larcom, Bendit and Mumma (*Virology*, **41**, 1; 1970) have been exercised to establish the molecular weights of the proteins. Molecular weight determinations on a polydisperse mixture of unfractionated proteins (in a non-ideal system to boot) is not usually a very rewarding occupation, but Larcom *et al.* estimate that in a dissociation, denaturing solvent, guanidine hydrochloride, a mixture of large and small components is present, the first having a reported molecular weight of 78,000. A partial chromatographic separation by size was also performed. The central finding in this work is that when a reducing agent, mercaptoethanol, is added to the denaturing solvent, the molecular weight of the large component drops to an estimated 48,000. This also happens when the sulphydryl groups in the protein are first chemically blocked, and it is suggested that disulphide-linked dimers may be present in the phage head.

These conclusions seem at odds with the results of work in other laboratories, and the molecular weight of the large component, which must comprise chiefly the 23-protein, has to be seen against a remarkable report by Kellenberger and Kellenberger–van der Kamp (*FEBS Lett.*, **8**, 140; 1970). They estimate molecular weights by the empirical but so far remarkably successful method of electrophoresis in polyacrylamide gels containing the detergent, sodium dodecyl sulphate. When the gene (number 31) for the "solubilizing protein" is rendered inactive by mutation, lumpy aggregates of the 23-protein appear in the head envelopes. When the protein is extracted from these, or from the tubular polyheads (gene 20 silent), a molecular weight of 61,000 is derived. Normal capsids, however, lead to a value for the same component of 49,000. The difference persists after treatment with guanidine hydrochloride and mercaptoethanol. Although it is still far from proven, the most convincing explanation is that one of the head proteins, functioning as a protease, causes the loss of a fragment of the 23-chain during the final stage of assembly. Components corresponding in size to the molecular weight deficiency have in fact been observed in the gel electrophoresis. If this scheme turns out to be correct, it will make an interesting dent in the mystique of self-assembly, which in this case at least could no longer be seen as a thermodynamically reversible process, governed only by the intrinsic physical properties of the proteins in the system.

PHOTOBIOLOGY

Co-factors and Chloroplasts

from a Correspondent

THE biochemistry of electron transport was the principal theme of the meeting of the British Photobiology Society at King's College, London, on June 10. Dr A. Trebst (Ruhr University, Bochum) described the isolation of a chloroplast component (S_L-eth) which seems to function in the electron transport chain between photosystem 1 and ferredoxin. The component was isolated using two antibodies to chloroplasts which inhibit ferredoxin-dependent reaction; one apparently reacts with the complete co-factor, the other with its prosthetic group. The co-factor, which, contrary to earlier reports, seems to be identical to San Pietro's ferredoxin reducing substance, has a molecular weight of 5,000. It is spectroscopically undistinguished, with a single absorption peak in the 260–270 nm region. The nature of the prosthetic group is not yet known.

Dr D. A. Walker (Imperial College, London) and Dr J. Wiskich (University of Bristol) described experiments on oxygen evolution by "whole" chloroplasts. Walker proposed that a criterion for the "wholeness" of chloroplasts in a suspension might be their ability to use flavin-adenine dinucleotide (FAD) as electron acceptor, intact chloroplasts being unable to take up FAD. He presented evidence that intact chloroplasts are also impermeable to adenosine triphosphate (ATP) and nicotinamide–adenine dinucleotide phosphate (NADP). Wiskich presented data on control ratio and P/2e ratio (1·6) in unbroken pea chloroplasts. These chloroplasts would not meet Walker's criteria for intactness, and the dangers of measuring P/2e ratio and other parameters in mixed populations of whole and broken chloroplasts were discussed.

Drs M. C. W. Evans and R. V. Smith (King's College, London) described the preparation of cell free nitrogenase from the photosynthetic bacterium *Chloropseudomonas ethylicum* and the blue–green alga *Anabaena cylindrica*, and the relationship of nitrogenase to the photochemical system. Nitrogenase from both organisms is similar to that from non-photosynthetic bacteria requiring ATP and a low potential reductant. In *Cps. ethylicum* the reductant may be ferredoxin, photoreduced by photosynthetically active particles from the bacterium. Reduced ferredoxin does not function with nitrogenase from *Anabaena* and the nature of the natural electron donor is unclear.

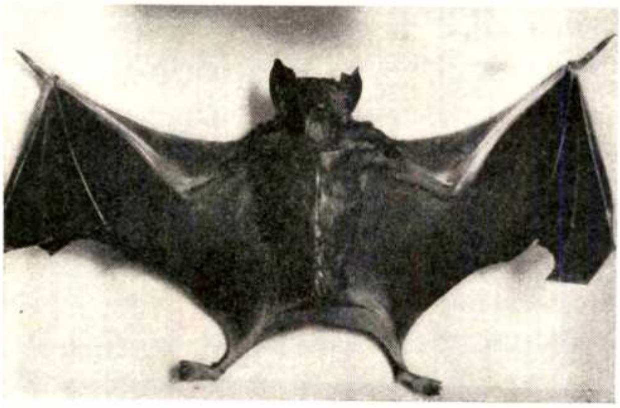
Dr A. R. Crofts (University of Bristol) reported the investigation of rapid *p*H changes induced in chromatophores of *Rhodopseudomonas spheroides* by illumination with laser and xenon arc flash. Using mutants deficient in carotenoids it was possible to correlate the rapid binding of protons, measured using bromocresol purple as indicator, with electron transport in the chromatophores measured by changes in the redox state of cytochrome *b*. It was found that 1 proton was bound per 120 chlorophyll molecules in the untreated chromatophores or 2 in the presence of valinomycin and antimycin A. The results were interpreted as indicating the transport of protons in accord with the chemiosmotic hypothesis involving two chromatophore components.

ZOOLOGY

Research at Regent's Park

VAMPIRE bats stole the limelight when the Zoological Society of London held the first open day at its animal hospital and research institutes in Regent's Park on June 11. Although in Trinidad the blood sucking vampire bats are pests, constantly pursued by the government bat catchers, the colony at the Nuffield Institute of Comparative Medicine is valued for the properties of its saliva. A wound made by a vampire bat continues to bleed long after the beast has bitten because of the action of the saliva. Dr T. Cartwright and his colleagues have found that the saliva contains an enzyme, named desmokinase because of the bat's other name, *Desmodus rotundus*, which activates plasminogen to plasmin, which in turn breaks down blood clots.

Desmokinase, with a molecular weight of about 2 million, seems to be a proteolytic enzyme which cleaves a protecting peptide from the active site of plasminogen. The attack of desmokinase on blood clots *in vitro* proved more effective than that of the other activators of plasminogen now in use—urokinase and streptokinase. But purification of desmokinase is still in progress and there will be a long time to wait before clinical trials can begin on a potential new treatment for sufferers from thrombosis.



Vampire bat.

Schoolboys and students, too, can expect to benefit from the fruits of the labours in the Nuffield Institute, for Dr G. H. du Boulay is preparing an atlas of radiograms of the cerebral arteries of mammals. So far he has injected the arteries of dead specimens of more than a hundred species and made radiograms from them. Early volumes are in the press, and when the atlas is complete its author hopes that it will become a revered guide for dissection, updating the classic work of nineteenth century anatomists.

Activity in the Wellcome Institute of Comparative Physiology centres on reproduction in various exotic animals which have not previously been familiar inhabitants of laboratories. Dr B. J. Weir has a collection of hystricomorph rodents from South America, including the tuco-tuco (*Ctenomys talarum*) which unexpectedly developed diabetes in captivity. The degu (*Octodon degus*) bred so successfully that its numbers increased seven-fold in its first year of captivity. The chinchilla (*Chinchilla langer*), however, is far less fertile, which leads to problems for commercial breeders. The reproductive difficulties of chinchillas arise because they have long heat cycles within a restricted breeding cycle, and also have a long pregnancy, so that opportunities for conception are limited. Pregnant mare's serum and human chorionic gonadotrophin have been injected to induce fertility, with the consequence that successful mating was followed by normal pregnancy and the birth of normal numbers of young.

The next step is to inseminate semen artificially from chosen males to propagate desired characteristics of fur quality and reproductive capacity. Advice will doubtless be on hand from Dr R. C. Jones, who is studying the problems of preserving mammalian semen for artificial insemination. Although many millions of cows have been inseminated with deep frozen sperm, the semen of some species deteriorates unless it is used when fresh. Dr Jones is looking at the injurious effects of freezing on sperm of various animals, including zebra, chimpanzee and boar, a species which presents particular problems of sperm preservation. Artificial insemination may well provide the means of preserving species in danger of extinction.

POLLUTION

Take a Deep Breath

from a Correspondent

CONCERN for the effects of atmospheric pollutants on the lung was reflected in the theme of the annual Hanford Biology Symposium, held from June 2 to 5 at Richland, Washington. A notable feature of the meeting was the increasing interest in attempts to define effects of pollutants not only in terms of pulmonary structural and functional changes affecting gas exchange, but also in terms of the underlying biochemistry. The cells in the lung have always seemed to biochemists much less active and interesting than cells of the liver, kidney, heart, brain and other organs, but now lung biochemistry has emerged as a discipline in its own right. Several contributions were devoted to analyses of metabolic pathways in lung cells, which have certain peculiarities.

Much attention was given to lipid synthesis in the lung in an attempt to understand the formation and turnover of the surfactant which, by reducing surface tension at the liquid–air interface, helps to maintain open airways. One of the pioneers of this work, Dr J. A. Clements (University of California, San Francisco), reported that in the lungs of eleven vertebrates, varying from reptiles to man, the abundance of surfactant and its principal component, dipalmitoylphosphatidylcholine, is related to the area of the respiratory surface, whereas the quantities of other lipids reflect pulmonary mass and diet. How many surfactant components exist is still unknown, nor has its composition provided clues to differences in susceptibility to adverse environments—although surfactants represent an obvious possible target. Several investigators, notably Dr J. Gil (University of Berne, Switzerland), have developed methods for preserving a layer of material over the alveolar epithelium in electron micrographs, and most experts agreed that this probably corresponds to surfactant. Dr O. K. Reiss (University of Colorado) and his colleagues have shown that a specific thiolacetate esterase is liberated from the lamellar bodies of the type 2 epithelial cells and is apparently related to surfactant.

Several contributors dealt with the origin and biochemistry of alveolar macrophages. Dr M. A. Brunstetter and her colleagues (University of California, Davis) used chimaeric mice with esterase (*Es*-2) markers to show that most alveolar macrophages originate from bone marrow. Several pollutants have been found to affect the capacity of alveolar macrophages to kill organisms, this being the principal mechanism by which the lung resists bacterial infections. Some of the most striking effects on macrophages are produced by particulate pollutants, such as silica and asbestos, as described by Dr A. C. Allison (Clinical Research Centre, London).

Of the gaseous pollutants, most work has so far been carried out with oxidizing atmospheres, such as high oxygen, ozone or nitrogen dioxide. These oxidize lipids and produce marked changes in lung structure and function. The structural changes following exposure to pure oxygen at one atmosphere, described by Dr E. R. Weibel (University of Berne, Switzerland), included degeneration of endothelial and type I alveolar epithelial cells and replacement of the latter by type II epithelial cells.

GALAXY FORMATION

Link with Expansion of Universe

from our Cosmology Correspondent

THE plausibility of the Eddington–Lemaître equations as representing the true mathematical description of our universe has been considerably enhanced by calculations which show that not only can galaxies form and grow in such a universe in a reasonable time, but that this process is itself inextricably linked with the expansion of the universe. Since Lifshitz's work more than twenty years ago, galaxy formation has posed a considerable problem to cosmologists, because it seemed clear that the universe just is not old enough for galaxies to have evolved from local condensations in an approximately homogeneous cloud of gas. This has caused models to be suggested in which either more complex cosmologies are required or special conditions are imposed to enable galaxies to grow. Recently R. Simon has developed the proposal of W. C. Saslaw that long range forces of gravitational attraction may be important in the growth of irregularities, producing density waves with wavelength close to the Jeans length.

Simon's calculations confirm this possibility, but of even greater significance is his discovery that another peak in the spectrum of possible density waves becomes significant for late epochs in the history of the universe. Unlike the peak corresponding to the Jeans length, which remains constant and can produce condensations of around galactic mass, the second peak moves in the direction of larger wavelength as the universe evolves and becomes increasingly significant (*Astron. Astrophys.*, **6**, 151; 1970). It is tempting to interpret this behaviour as implying that the galaxies formed by the condensations due to the first wave will become clustered about the maxima in the second wave, and that these clusters of galaxies will move away from each other (with relative velocities proportional to their separations) due to the increase in wavelength of the second wave. Clearly this picture is most agreeably consistent with observations, while providing the long sought after clue as to why the Eddington–Lemaître model affords a good description of the universe.

Detailed questions of why galaxies have the variety of structure which is observed, and how stars form from the protogalaxies, remain to puzzle theorists interested in the formation of galaxies.

COMETS

Silicate Grains in Comet Bennett

by our Astronomy Correspondent

THE infrared astronomy group at the University of Minnesota, last year one of the teams that presented evidence for the presence of silicate grains in the interstellar dust (*Nature*, **222**, 326; 1969), has reported what seems to be the silicate emission feature in the spectrum of Comet Bennett (R. W. Maas, E. P. Ney and N. J. Woolf, *Astrophys. J. Lett.*, **160**, L101; 1970). The comet was observed on April 4 with a thirty inch telescope at wavelengths between 2 and 20 microns, and an emission feature was detected at 10 microns. This seems to be the feature already detected in emission from cool stars and from the Orion nebula, and in absorption in the spectrum of the cool supergiant 119 Tauri. In a series of papers in *Astrophys. J. Lett.* last year the feature at 10 microns was attributed to the presence of silicate grains (**155**, 181–199; 1969).

The experiment on Comet Bennett is interpreted by the Minnesota group as confirmation that the 10 micron feature is indeed probably due to a silicate or a combination of silicates. The association between comets and meteor streams—which has long been well established—indicates the probable presence of silicate grains within comets. Although the finely divided particles which make up meteor streams are almost certainly in a different class from the more substantial objects which survive the flight through the atmosphere and which have a known composition, evidence for silicate elements in shower meteors comes from the optical spectra seen as meteors burn up in the atmosphere. Thus the detection of the 10 micron feature in a location where silicates are expected is accepted by the Minnesota group as adding some weight to the silicate hypothesis. But in line with the current view that interstellar dust is as likely as not a mixture, chiefly of silicates and graphite, the group say their infrared data point to a second refractory material in the nucleus of Comet Bennett which could easily be carbon.

HUBBLE SEQUENCE

New Light on Galaxy Evolution

from our Cosmology Correspondent

THE evolution of galaxies and the reasons for the existence of the different categories of galaxies have yet to be explained with anything like the confidence which can be placed in the accepted models of stellar evolution. But the progress being made in the investigation of these problems is emphasized by P. Brosche, who has incorporated several recent developments in a model where the Hubble sequence is interpreted as an angular momentum sequence of galaxies of roughly equal mass (*Astron. Astrophys.*, **6**, 240; 1970).

It is assumed that star formation simply occurs when the gas making up a protogalaxy becomes sufficiently dense for local regions to collapse under their self gravitation, and on this interpretation protogalaxies with small angular momenta shrink relatively rapidly, becoming relatively dense and converting most of their mass into stars before they can become highly flattened, so that they form the elliptical nebulae. The galaxies with more angular momentum convert only a small percentage of their mass into stars before they become highly flattened, resulting in a distribution of stars within a disk as seen in the spiral nebulae. Models of this type require a mechanism for the release of energy during the collapse of a protogalaxy, and in this particular case the efficiency of the mechanism must be linked to the angular momentum of the protogalaxy. Brosche favours a process involving collisions of interstellar gas clouds, the number densities of which have been estimated as 10^6 per kiloparsec for our galaxy. The energy loss considered is the macroscopic kinetic energy of these gas clouds, not the thermal energy of the molecules, so that quasi-static evolution rather than a violent collapse is certainly plausible. Although many aspects of Brosche's work are so far rather unsophisticated, it seems to be pointing in a highly profitable direction. Measurements of the rotational velocities of elliptical galaxies (if not quasars!) and more advanced *N*-body calculations are the obvious means whereby both observational astronomers and theoreticians can contribute to its further development.

COMA CLUSTER

Missing Mass still a Problem

from our Observatories Correspondent

G. and A. de Vaucouleurs of the McDonald Observatory (University of Texas) have reported the results of a search for luminous matter between galaxies in the Coma cluster (*Astrophys. Lett.*, **3**, 219; 1970). Coma is one of the best examples of a cluster in which there is a "missing mass" problem. Measurements of the redshifts and projected separations of member galaxies have been used to infer the mass of the cluster through the virial theorem. This assumes, of course, that the cluster is a stable, self-gravitating system. The mass obtained from the virial theorem is about 7×10^{14} Suns, while the total mass of the visible galaxies is estimated to be about a factor of five less than this. Discrepancies of this kind are commonly found in clusters of galaxies. But whereas most clusters of galaxies appear as loose aggregates with little central condensation, the Coma cluster is a radially symmetrical, centrally condensed object which certainly looks to be in equilibrium.

There are several possible forms for the missing mass: intergalactic stars, neutral hydrogen, ionized hydrogen, molecular hydrogen and "black holes" have all been suggested. Some of these have already been ruled out. For example, neutral hydrogen in sufficient quantity would have been detected by its 21 cm emission, and ionized hydrogen hotter than a million degrees would produce detectable X-rays.

The de Vaucouleurs searched for luminous matter—emitting gas or intergalactic stars—by scanning across a diameter of the cluster, which is about a degree across, with a sensitive pulse-counting photometer. They determined the mean sky background well away from the cluster and found that in blue light this was equivalent to one star of magnitude 22·3 every square second of arc. This background is mostly due to terrestrial airglow rather than to the integrated luminosity of faint stars and galaxies. A small excess luminosity extending over 30–45 minutes of arc centred near the geometrical centre of the cluster was detected. The peak of this excess brightness was only 26·2 magnitudes/s^2. The overall "intergalactic" luminosity amounted to 40 per cent of the accepted value for the integrated luminosity of cluster galaxies, however.

This excess luminosity is not interpreted as being truly intergalactic (due to stars which are not bound to any particular galaxy). Instead, the de Vaucouleurs conclude that it can be substantially accounted for by the overlapping coronas of the two supergiant elliptical galaxies, NGC 4874 and NGC 4889, which lie at the centre of the cluster, and a few others. Measuring the total luminosity of a galaxy is a long standing problem in astronomy. As Hubble found, the luminosity per unit area goes down almost as the square of the radius in the outer parts of a galaxy, so that it merges imperceptibly into the background sky with a still substantial contribution coming from the outer parts. The de Vaucouleurs estimate the effect of the corona of NGC 4889 by comparing the luminosity profile of its inner parts with that of the nearby, isolated, supergiant elliptical, M 87. The luminosity profiles agree when suitable allowance is made for the different distances of the two galaxies. Recent work by Arp and Bertola, and by G. de Vaucouleurs, on M 87 itself showed that this galaxy, which on photographs has an apparent diameter of less than 4 minutes of arc, is in fact at least a degree across. Others had used sky comparison areas about 30 minutes of arc away from M 87 and the revised measurements raised its total luminosity by half a magnitude. The de Vaucouleurs' measurements of the Coma cluster led them to increase the luminosities of the two supergiant galaxies in the Coma cluster by the same factor.

The upward revision by 40 per cent of the total light from galaxies in the Coma cluster does little to relieve the "missing mass" problem. The mass-to-light ratio required to bind the cluster is still about 200 solar units. For normal elliptical galaxies with mass and light distributions that have been measured, this number does not exceed about 50.

ISLAND MOVEMENT

Dissent on Madagascar

from our Geomagnetism Correspondent

THE assertion by Strong and Flower (*Earth Planet. Sci. Lett.*, **7**, 47; 1969) that Madagascar has been in its present position relative to Africa since the late Carboniferous, and probably since the Pre-Cambrian, has been strongly criticized by Wright and McCurry (*Earth Planet. Sci. Lett.*, **8**, 2671; 1970). Strong and Flower based their conclusion on the existence of sandstone inclusions in some of the lava flows on the Comores Archipelago which separates the Mozambique Channel from the Somali Basin (see map, *Nature*, **225**, 11; 1970). This, they claimed, provides "unequivocal evidence that this part of the Indian Ocean is underlain by non-oceanic crust".

Wright and McCurry disagree with this. They suggest that slightly metamorphosed sandstone inclusions in basalts of the Comores Archipelago are evidence only that beneath some of the volcanoes there are arenaceous sediments, fragments of which have been carried to the surface and baked by the ascending lavas. In short, they feel Strong and Flower draw too strong a conclusion. They agree that the evidence against a southward movement of Madagascar, in particular the fact that the sense of displacement (sinistral) along fracture zones in this area of the Indian Ocean is in the wrong direction, is too strong to be denied—but disagree that the island has thus stayed put. They point out that a case may still be made for an older proposal that Madagascar followed India and the Seychelles north-eastwards, having originally occupied the Inhambane delta region north of Lourenço Marques. Although this interpretation conflicts with some of the geological evidence, it is consistent with the sense of the transcurrent faulting in the South-West Indian Ocean and yet is not inconsistent with the presence of sandstone inclusions in the Comores lavas. The debate will no doubt continue.

RNA at Cold Spring Harbor

from our Special Correspondent

THE view that classical molecular biology is played out, with no significant questions awaiting answer, was refuted by this year's symposium at Cold Spring Harbor on RNA transcription. With a wide range of systems covered, new control elements in bacteria and bacteriophages were reported as well as new enzyme activities in mammalian cells.

The sequences of the single stranded RNA phage R17 now known amount to almost 500 of 3,500 nucleotides (Fig. 1) and those of *E. coli* 16S ribosomal RNA to 200 out of 1,600 residues. The first hundred nucleotides from the 5′ end of R17 comprise a sequence which cannot code for any of the three proteins which the phage specifies, but S. Cory, J. M. Adams and P. Spahr (Institut de Biologie Moléculaire, Geneva) were not too surprised by this finding, for much the same is true for another RNA phage, Qβ. The last fifty nucleotides at the 3′ end of the R17 phage may also remain untranslated. The only termination sequence so far determined (for the coat protein gene) has two successive nonsense codons; the 3′ terminal region has no such sequence and so cannot specify protein if a double terminator is a general requirement.

Comparison of the 5′ terminal sequence of R17 with that of Qβ shows a surprising degree of homology—surprising because the two phages do not seem to be related serologically. The 5′ terminal sequence of R17 probably folds into two hairpin loops. The first (residues 1–29) shows extensive homology with the starting region of Qβ. The sequence of the second loop of R17 (residues 37–74) is also homologous with Qβ, not with the analogous region but with a sequence between Qβ residues 101 and 128. This suggests that R17 and Qβ may have descended from a common ancestor, a region of which was deleted in R17 at some point after evolutionary separation. The conservation of sequence at the immediate 5′ terminal region suggests that, although not translated into protein, this region must have some function which is so important for the phage that it has been preserved through evolution.

Another remarkable homology is that between the 3′ terminal sequences of the plus and minus strands of the phage. In phage replication, an RNA replicase enzyme attaches to the 3′ end of the infecting (+) strand and synthesizes a complementary (−) strand. When this is complete, the enzyme attaches to the minus 3′ end and synthesizes a plus strand. Only the plus strand has been sequenced directly, but the nucleotide sequence of the minus strand can be deduced from its complementarity with the plus strand.

Both strands have an identical sequence of six nucleotides at their 3′ terminus

$$\begin{array}{r|c|l} \cline{2-2} \ldots\ldots\ldots\ \mathrm{G\,U\,U\,A} & \mathrm{C\,C\,A\,C\,C\,C} & \mathrm{A{-}OH}\ \ 3'\ \text{plus} \\ \ldots\ldots\ldots\ \mathrm{G\,G\,U\,C} & \mathrm{C\,C\,A\,C\,C\,C} & \mathrm{C{-}OH}\ \ 3'\ \text{minus} \\ \cline{2-2} \end{array}$$

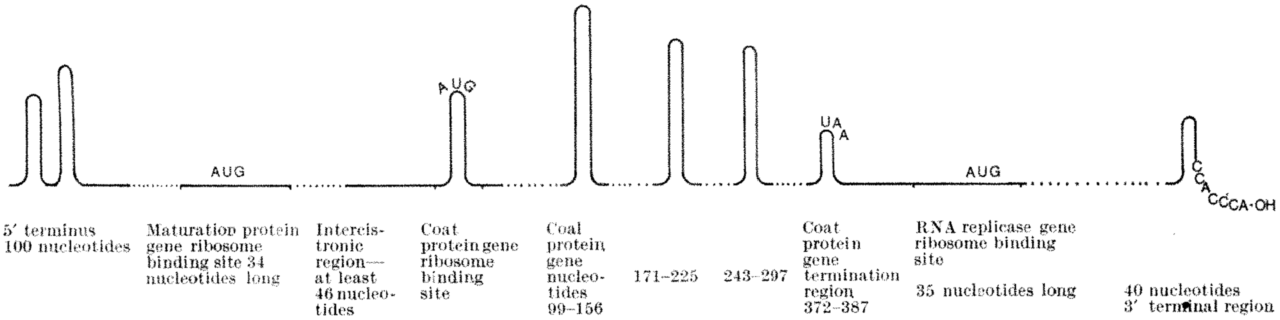
and this common sequence may be the recognition site for the RNA replicase. This is supported by the finding that, although the last 3′ nucleotide can be removed without affecting the infectivity of the phage, any further degradation causes a large decrease in infectivity. The proposed sequence is just large enough to provide sufficient specificity; any given six nucleotide sequence would occur about one in four thousand times by chance, and the phage is some 3,500 nucleotides long.

Sequences of more of the coat protein gene were reported by P. G. N. Jeppesen, J. L. Nichols, F. Sanger and B. G. Barrell (MRC Laboratory of Molecular Biology, Cambridge). It now looks as though much of the phage forms hairpin loops. The RNA folds back on itself in at least three parts of the internal regions of this gene and also at its beginning and end. It seems likely that this reflects a need to pack the RNA within its protein coat, and there is speculation that it may also be used as a mechanism for controlling its translation.

16S ribosomal RNA from *E. coli* contains not only hairpins but also the looped regions joined by double stranded stems characteristic of transfer RNA. P. Fellner, C. Ehresmann and J. P. Ebel (Laboratoire de Chimie Biologique, Strasbourg) reported that the 200 residues so far sequenced suggest that the rRNA may have a structure much like a giant tRNA.

Sigma Action

The symposium showed that the control of transcription is turning out to be a complicated process which may involve any of the subunits of RNA polymerase. The *E. coli* enzyme consists of four types of subunits associated in the structure $\alpha_2\beta\beta'\sigma$. Sigma determines the specificity of initiation in bacterial cells and is released from the DNA-enzyme complex shortly after initiation, leaving the $\alpha_2\beta\beta'$ core enzyme to elongate the RNA chain. How does sigma control the initiation of transcription? When core enzyme transcribes DNA *in vitro*, it initiates RNA synthesis at random sites. When sigma is added, initiation is restricted to certain sites—probably those which are used *in vivo*. D. Hinckle and M. Chamberlin (University of California, Berkeley) reported that core enzyme by itself



AUG

AUG
CCACCCA·OH
5′ terminus 100 nucleotides
Maturation protein gene ribosome binding site 34 nucleotides long
Intercis-tronic region—at least 46 nucleotides
Coat protein gene ribosome binding site
Coat protein gene nucleotides 99–156
171–225
243–297
Coat protein gene termination region 372–387
RNA replicase gene ribosome binding site
35 nucleotides long
40 nucleotides 3′ terminal region

Fig. 1. Secondary structure of RNA phage R17 for the 500 nucleotides which have been sequenced. The phage is about 3,500 nucleotides long and the drawing is not to scale. About 70 per cent of its length probably forms base paired loops.

associates non-specifically with DNA in a loose binding which is rapidly reversible. Sometimes, by chance, the core will bind at a promotor site (where synthesis is initiated *in vivo*). Interaction with sigma forms a more stable complex in which the enzyme is tightly bound and can no longer dissociate from the DNA. This ensures preferential initiation of transcription from tight binding sites.

It is not clear exactly how sigma stabilizes the complex. Hinckle and Chamberlin suggested that it may either itself directly recognize the nucleotide base-pair sequence of the promotor site, or do so indirectly by effecting an allosteric change in the core when this is located at a promotor. But W. Zillig *et al.* (Max Planck Institut für Biochemie) showed that instead it recognizes an initiation site which is adjacent to the primary binding site. Both groups, however, agreed that sigma opens the DNA duplex for the start of transcription. Initiation depends on temperature in a way which suggests that the first step in RNA synthesis is the action of sigma to melt the DNA to produce a region of local unwinding.

Although attempts to discover more than one kind of sigma factor in *E. coli* have failed, the production of new sigma-like factors plays an important part in controlling the development of bacteriophages. Immediately after entry into a bacterium, phage T4 DNA is transcribed by the host RNA polymerase. This transcription is specific for the "immediate early" genes of the phage. If chloramphenicol is added, these genes are still transcribed, but a second class of early genes, the "delayed early", can no longer synthesize RNA. This suggests that their transcription requires the synthesis of a phage-coded protein, and this has proved to be a sigma-like factor which directs the core enzyme of the host to transcribe the delayed early and also some of the immediate early genes.

Subunits of the core enzyme are also changed during infection. The α subunit is modified early on, but this does not affect the specificity of transcription. The β′ subunit is modified later, about 15 min after infection. A. A. Travers (Harvard University) reported that, after this modification, the core has a much lower affinity for sigma, and this is probably responsible for the shut-off of early genes which occurs at this time. Late genes can be transcribed only after a second phage-coded sigma-like factor has been synthesized; this directs the modified core to synthesize late mRNA from T4 DNA *in vitro*.

But *in vivo*, transcription of late genes seems to be coupled to DNA replication. E. P. Geidescheck *et al.* (University of Chicago) have found that when temperature sensitive mutants in the gene which codes for the phage DNA polymerase are raised to the non-permissive temperature, late mRNA synthesis is reduced by 90 per cent as soon as replication ceases. The transcription depends on concurrent replication, and the phage DNA goes through a cycle in which it enters a competent state when it is replicated and soon becomes incompetent again. This suggests that it is physical state of the DNA which is important. The use of ligase mutants showed that the action of this enzyme is needed to convert the DNA to the incompetent state. This suggests that transcription of late genes requires the gaps in the DNA which are produced by discontinuous replication. One model to reconcile the *in vitro* and *in vivo* results suggests that the T4-early sigma-like factor cannot be displaced from the core *in vivo* by the late sigma-like factor. Binding to gaps in the DNA may effect release of the early sigma, thus permitting its replacement by the late sigma.

Sporulation in *B. subtilis* also demands changes both in a sigma-like initiating factor and in core subunits. R. Losick, A. L. Sonnenshein and R. L. Shorenstein (Harvard University) have used the bacteriophage φe which grows on vegetative but not on sporulating bacteria. *In vitro*, RNA polymerase extracted from vegetative cells, but not from sporulating cells, can transcribe the phage. Although the vegetative core enzyme does not transcribe φe DNA, activity is restored by addition of either vegetative *B. subtilis* initiating factor or *E. coli* sigma factor. When enzyme from sporulating bacteria was used, neither initiating factor nor sigma factor enabled the sporulation core to synthesize RNA. Comparison of the subunits of the two cores showed that one of the B subunits of the vegetative enzyme was replaced in the sporulation enzyme by a different polypeptide with a molecular weight reduced from 155,000 to 110,000. This change probably accounts for the switching off of vegetative genes at sporulation. Losick is now looking for a new initiating factor which will use the modified core to turn the sporulation genes on.

Termination of Transcription

Hopes that the action of the rho factor might provide a simple model to explain all terminations of RNA synthesis were dashed at the symposium. To be sure, rho interacts with RNA polymerase at specific sites on the DNA template to release RNA chains *in vitro*, but specific termination can also take place *in vitro* in the absence of rho.

Transcription of lambda DNA *in vitro* is initiated at two sites, one on the *l* strand and one on the *r* strand. J. W. Roberts (MRC Laboratory of Molecular Biology, Cambridge) reported evidence from Harvard that, in the absence of rho factor, both RNA products remain associated with the fast-sedimenting transcription complex. When rho is added, transcription is terminated at a specific site on each strand to release the distinct RNA species characterized as 12S and 7S.

Rho has much the same effect with phage T4 DNA as template *in vitro*, if the salt concentration is low. J. P. Richardson (University of Washington) found that rho limits transcription to the immediate early genes. When the termination factor is omitted from the reaction mixture, the RNA products are larger and contain sequences in addition to those representing the immediate early genes; this is probably caused by the RNA polymerase reading past the termination signals.

Increasing the concentration of KCl, however, decreased the efficiency of rho-mediated termination, and above 0·15 M KCl, the same products were made with or without rho. But termination can still be specific even in the absence of rho. U. Maitra, A. Guha and A. Lockwood (Albert Einstein College of Medicine) showed that termination on T4 DNA *in vitro* takes place at specific sites when the salt concentration is high, but not when it is low. Rho is not needed for this effect.

After the complexity of the larger bacteriophages, reports of work with phage T7 introduced a note of refreshing simplicity. T7 DNA has a molecular weight of 26×10^6 and complementation mapping shows that there are at least nineteen genes. The last 0·7 per cent of the phage is terminally redundant, but is not circularly permuted (Fig. 2). Transcription is totally asymmetric and takes place only from the *r* strand. W. C. Summers and R. B. Siegel (Yale University) have found that there are two stages of RNA synthesis during infection. The shift from early to late synthesis requires the product of gene 1; this is probably a sigma factor which redirects

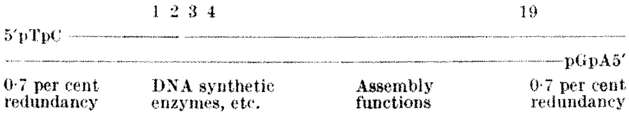

Fig. 2. Bacteriophage T7.

the activity of host core enzyme, for *in vitro*, *E. coli* RNA polymerase transcribes only early genes and the enzyme from T7-infected cells transcribes late genes. Sufficient mRNA is synthesized by transcription of only the infecting parental strand, with no need for replication of the phage; this RNA is remarkably stable for a bacterial system, with a half life of more than 15 min.

Initiation of synthesis of early RNA takes place at only one site on T7 DNA, yet Summers and Siegel have found four early RNA species in infected cells, of molecular weights 1·1, 0·45, 0·29, $0·20 \times 10^6$. A very different result is obtained *in vitro*. R. L. Millette and C. D. Trotter (University of Colorado) reported that, in a system without rho, T7 DNA directs the synthesis of only one RNA species, which has a molecular weight of about $2·1 \times 10^6$. This roughly totals the molecular weights of the four early RNAs.

Two types of termination may therefore be taking place *in vivo*. As RNA polymerase transcribes the DNA from the single initiation point, rho terminates transcription at each of three successive sites, but the enzyme does not dissociate from the DNA template. This termination might be achieved either by rho breaking the RNA chain at specified points after its transcription, or by a genuine termination event. The latter would require the RNA polymerase to re-initiate synthesis at an adjacent site, but without the benefit of sigma factor. When the polymerase reaches the fourth termination site, transcription is terminated and the enzyme dissociates from its template in reaction which does not need rho. The combination of hybridization techniques with electron microscopy provided another approach to this system. R. W. Davis and R. W. Hyman (California Institute of Technology) presented electron micrographs which showed the sites where particular RNA species hybridize to the DNA. When T7 DNA is visualized after denaturation and random renaturation, a tangle is seen. But if RNA is hybridized to the DNA, the DNA–RNA hybrid regions cannot renature, although the remaining regions of single stranded DNA can do so. The sites of hybridization can be located by using suitable visual markers on the DNA.

Native T7 DNA early after infection shows a clustering of RNA polymerase molecules at one end of the genome. This single initiation site is located about 1·3 per cent from the end of the DNA, so that it is outside the region of terminal redundancy. Early RNA hybridizes only with this end of the phage DNA. The number of polymerases attached to the DNA increases at the rate of about one a minute for about 15 min, and synthesis of RNA takes place at about forty-five nucleotides per second. The whole template can be transcribed into one large messenger; this is complete after about 25 min.

There is no termination of transcription in this system. This can be reconciled with the discrete messengers produced in other systems, however, because these use different strains of phage T7. Although all T7 strains derive from a single plaque (set up in 1947), there has been divergence into at least six strains. The course of infection is much the same irrespective of strain, but Davis and Hyman's strain seems to lack the termination–dissociation signal of Summers and Siegel's and Millette and Trotter's strain.

Looking at RNA Synthesis

Seeing is believing was also the theme of the most spectacular contribution to the symposium, from O. L. Miller and B. R. Beatty (Oak Ridge National Laboratory) and B. A. Hamalko and C. A. Thomas (Harvard University). Their visualizations of nucleolar DNA transcribing ribosomal RNA have been extended to bacterial systems. After rupture by osmotic shocks, the intracellular contents of *E. coli* fragile mutants were examined by electron microscopy.

Fig. 3 shows a thread of DNA running horizontally, with RNA strands attached to it at intervals. Each RNA chain meets the DNA template at a granule which is about the right size to be an RNA polymerase enzyme. All the RNA chains under transcription have ribosomes attached to them in fairly close packing; because virtually no free polysomes were seen, it is likely that the translation of messengers can take place only while they are themselves under synthesis. An operon can be defined by this technique as the region between the shortest polyribosome (the promotor end) and the longest (the terminator end).

How do these results correlate with earlier biochemical studies? Most operons seen in these pictures have about ten messengers attached at random intervals, with the largest polyribosome containing up to about twenty ribosomes. Just before the presentation of this paper, J. K. Rose, R. D. Mosteller, R. A. Baker and C. Yanofsky (Stanford University) announced a re-appraisal of some of the parameters of the *E. coli* tryptophan system. Their previous estimates that about three messengers each bearing ninety ribosomes should be attached to the operon at any give time have now been revised to suggest about fifteen messengers with up to twenty ribosomes each. The definite periodicity of transcription hitherto observed has proved unreproducible, and can now only be observed occasionally. This revision gives excellent agreement between the results obtained by biochemical and visual techniques.

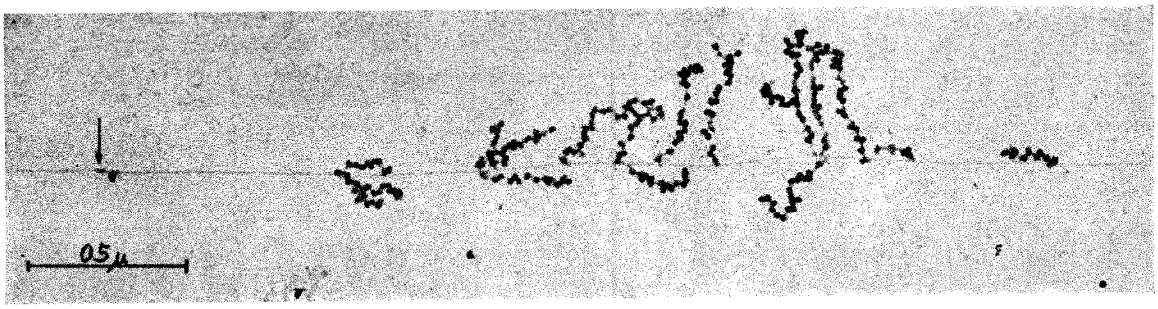

Fig. 3. Visualization of an operon of *E. coli*.

Control for Lactose Operon

Induction of the *lac* operon of *E. coli* requires 3′–5′ cyclic AMP both *in vitro* and *in vivo*. Among defective mutants which cannot respond to the nucleotide, R. L. Perlman *et al.* (National Institutes of Health) and G. Zubay (Columbia University) have identified strains which lack a protein which binds cyclic AMP. This protein, which may be partially purified from wild type bacteria, restores the ability of *in vitro* extracts of mutant cultures to induce the operon. It seems to act on RNA synthesis, consistent with its stimulation *in vivo* of transcription from the promotor.

It is difficult to pin down exactly what is happening in these systems because both transcription and translation are taking place. L. Eron reported that Beckwith's group at Harvard University have established a system which looks only at transcription. RNA is transcribed from a preparation of DNA of phage φ80 carrying the lactose genes. It is then hybridized with DNA from a lambda phage which bears the lactose genes. Because there is virtually no homology between the φ80 and lambda phages themselves, only RNA transcribed from the lactose genes can anneal to the lambda strands.

Transcription in this system depends completely on the presence of sigma factor. But even with the complete RNA polymerase, transcription is symmetrical and both DNA strands direct RNA synthesis. Addition of cyclic AMP and the partially purified binding protein, however, restricts transcription of the lactose operon to the correct strand of DNA. Nevertheless, it is not yet clear whether the system is working as it does *in vivo*. There is some suggestion that transcription may be initiated not at the *lac* promotor but at a site to the left of the regulator *i* gene. Another cause for disquiet is that transcription is not repressed by addition of the *lac* repressor. All the same, it is now clear that control of the lactose operon is more complicated than thought hitherto, and must require at least one more protein control factor.

Multiple RNA Polymerases

One session of the symposium was devoted to what was to prove essentially a workshop on mammalian RNA polymerases. Eleven groups reported their success in purifying the true polymerases. Although there were some reports that there may be three or even more distinct polymerases in animal cells, there was general agreement that there are two nuclear polymerases. One is associated specifically with the nucleolus and transcribes ribosomal RNA and the other is in the nucleoplasm and, presumably, makes messenger RNA.

Many papers concerned with bacterial RNA polymerase referred to the "wonder-drug" rifampicin which binds to the β′ subunit and inhibits transcription at or soon after initiation. Because chain elongation is not affected, the continued transcription of RNA in the presence of rifampicin implies that it must have been initiated before the drug was added. Unfortunately, its effect is confined to the bacterial enzyme; a counterpart for mammalian systems, however, was reported, and although α-amanitin has not yet earned the title of wonder-drug, it is being widely studied.

Its mode of action is not known, if only because the concentrations at which it inhibits different systems vary over at least a ten-fold range. But there is agreement that the type I enzyme, from the nucleolus, is not inhibited, while the type II enzyme, from the nucleoplasm, cannot synthesize RNA after addition of α-amanitin. Use of this criterion shows that comparable enzymes are present in all the various animal cell types studied.

Another cytological observation made its contribution to molecular biology in the discussion on mammalian polymerases. Addition of α-amanitin to salivary glands prevents the formation of puffs along the chromosome (presumably where messenger RNA is synthesized), but does not inhibit the synthesis of RNA at the nucleolus (which continues to incorporate a precursor into RNA).

Central Dogma Inverted

Reports of new types of enzyme activities filled the closing sessions of the symposium. A. J. Shatkin and A. K. Bannerjee (Roche Institute of Molecular Biology), and W. K. Joklik, J. J. Shehel and H. J. Zweerink (Duke University Medical Center, North Carolina) reported that the virion of reovirus (a double stranded RNA virus) contains an RNA-dependent RNA polymerase which synthesizes RNA by a completely conservative mechanism; it is analogous to DNA-dependent RNA polymerase and transcribes messenger from the genome without affecting the integrity of the template. Presumably, another enzyme must be responsible for replicating the RNA parental duplex by a semi-conservative mechanism.

Fig. 4. Segments of the genome of reovirus.

Reovirus is also notable for the state of its genome, which was shown by S. Millward (Wistar Institute, Philadelphia) to comprise ten different segments which can be separated on polyacrylamide gels. Each segment has a 5′ end which consists of a single stranded length of about six purines, probably guanines (Fig. 4). This means that the different segments cannot join together, either covalently or by overlapping of complementary single-stranded sticky ends. How the virus selects one copy of each segment for its virion is now under study.

The discovery that RNA can act as template to direct the synthesis of DNA provided a dramatic finish for the symposium. It has been known for some time that inhibitors of DNA synthesis can prevent the successful infection of animal cells by certain RNA viruses. D. Baltimore (Massachusetts Institute of Technology) reported results similar to those discussed by Temin at Houston (*Nature*, **226**, 1003; 1970). Baltimore found that an RNA-dependent DNA polymerase activity is located inside the virion of Rausch mouse leukaemia virus and Rous sarcoma virus (both single stranded RNA viruses). The enzyme is presumably coded by the virus.

What sort of DNA does this enzyme synthesize ? It seems likely that the immediate product is a DNA–RNA hybrid. This might then synthesize a duplex DNA by displacement of the RNA strand, and such DNA could replicate and might be integrated into the genome of the host cell. It could also direct RNA synthesis, as indeed might the DNA–RNA hybrid itself.

Earlier, H. Stein and P. Hausen (Max Planck Institut für Biologie) had reported that, when purifying a factor that inhibited RNA synthesis on denatured DNA templates, they found an enzyme which degrades DNA–RNA hybrids. Its action is a specific degradation of the RNA strand only. The apparent absence of any function *in vivo* for this enzyme may have been filled by Baltimore's study; perhaps it is concerned in some way with defending animal cells against viral invaders.

Solar Eclipse of March 7, 1970

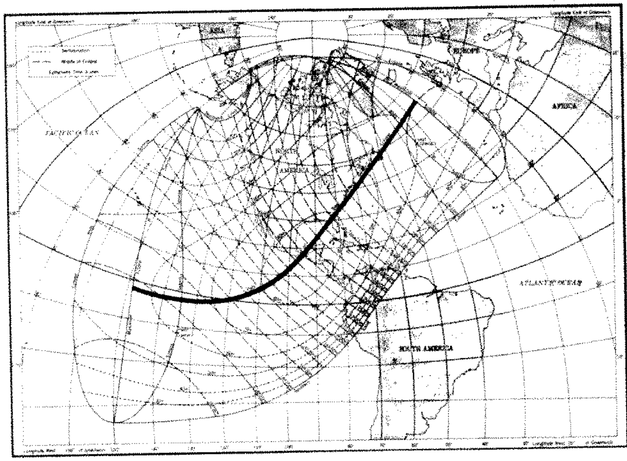
Eclipse not Spoilt by Shortage of Funds

The total eclipse of the Sun on March 7 this year was obviously a great adventure for everybody who took part. For many people the search for an observing site where the probability of clear skies would be greatest meant a trip to central America, where the path of the eclipse crossed southern Mexico before sweeping over the Gulf of Mexico and north along the east coast of the United States, Nova Scotia and Newfoundland, coming to an unremarked end in the North Atlantic halfway to Ireland. But the most bizarre anecdote belongs to the Naval Research Laboratory. They had to call in the salvage department of the United States navy when their rocket experiment to catch the ultraviolet flash spectrum of the Sun sank in the Atlantic after a parachute failure. Fifteen days after the eclipse the payload was rescued from a mile beneath the sea, with one set of photographs miraculously still intact (see page 1132).

Why do people still go to such lengths to record an eclipse ? After all, it must count as one of the longest standing activities of the astronomer. A hundred years ago in the columns of *Nature*, Norman Lockyer was canvassing support for expeditions to Spain and to Sicily to observe the eclipse of December 1870, when the burning question apart from whether government help would be forthcoming was the nature of the corona. Surely by now solar eclipses must have been squeezed dry of all the information that they have to give ?

The reports in the pages that follow show how far this is from being the case. For a start, the perfection of the rocket has revitalized the study of the Sun as it has the rest of astronomy. By recording the spectrum of the rim of the Sun as the Moon inches its way to second contact, the properties of successively higher layers in the chromosphere can be determined. With guidance systems now available so that a rocket can latch on to the decreasing crescent of the eclipsed Sun the flash spectrum can be recorded into the ultraviolet. This was the impetus behind the Naval Research Laboratory experiment, and behind a more successful experiment involving an international group from Britain, Canada and the United States (see *Nature*, **226**, 249; 1970).

Since the 1920s, and the work of Appleton in particular, eclipses of the Sun have come to be red letter days for atmospheric scientists as well as astronomers. Indeed, nearly half of the reports which follow are to do with what happens to the atmosphere, chiefly the ionized part, when the solar radiation is blotted out. Partly as a result of soundings during solar eclipses it is now well established that the lower ionized layers, the D-region at around 75 km altitude and the E-region around 110 km, are maintained by solar X-rays and ultraviolet, and that the F layers which are at their most prominent near 170 km (the F1-region) and near 300 km (the F2-region) are maintained by extremely short ultraviolet radiation. Obviously the eclipsing Moon is a first rate piece of apparatus by which the solar radiation is rapidly obliterated so that the processes which govern the decay of the ionization can be studied without the complications appertaining at sunset. This time it was possible to measure how the total number of electrons in a column of the atmosphere was altered, by observing the Faraday effect on polarized signals from several geostationary satellites (see page 1111, for example). It will also no doubt turn out to be important that the Canadian satellites which use a miniature ionosonde to investigate the topmost reaches of the ionosphere—out of bounds for ionosondes on the ground because of absorption—were able to probe several areas in the penumbra. It is also splendid that the path of totality was sufficiently close to Puerto Rico to make it worth using the powerful radar at Arecibo to determine electron concentrations, and electron and ion temperatures throughout the atmosphere (see page 1124). This technique is based on the Thomson scattering of radar pulses by free electrons to obtain data over a wide spread of heights, but it requires very high power radar transmitters and large collecting surfaces such as the aerial at Arecibo, still sufficiently rare for people to be pleased that the penumbra crossed the Caribbean.



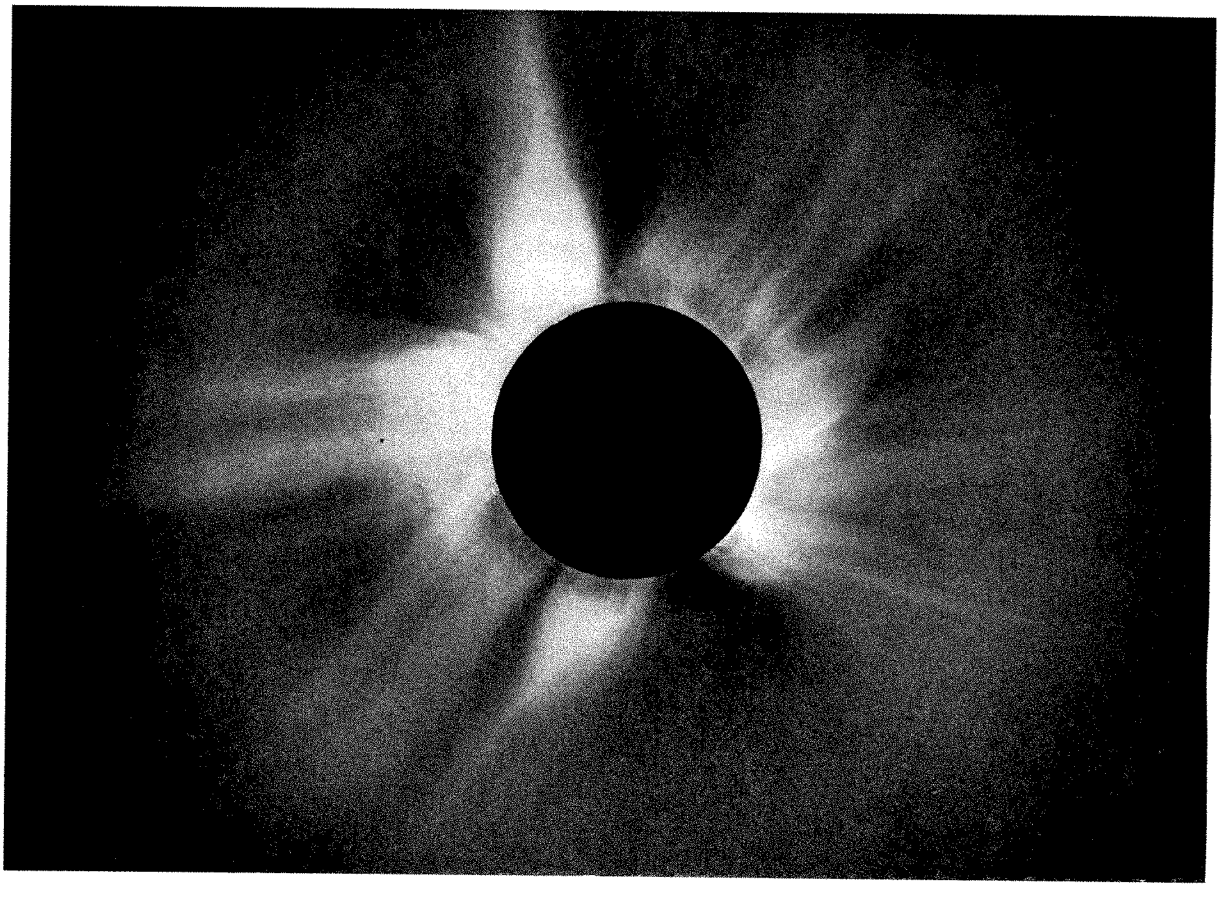
The path of totality, from *The American Ephemeris and Nautical Almanac.*

With experiments of this kind throwing light on the mechanisms governing the production and loss of ionization, and on transport processes in the ionosphere, it is satisfying that the March eclipse should have something to say about the way oscillations can be initiated in the atmosphere. Since 1960 when Hines resurrected interest in what are called atmospheric gravity waves—adiabatic waves for which gravity is the restoring force—the fashion has been to interpret the random motions which undeniably occur in the upper atmosphere in these terms, and it now seems that the perturbation of the atmosphere by the eclipse may have been enough to set up an oscillation (see page 1123). Indeed, the oscillation in the total number of electrons as recorded at Stanford uncannily matches the prediction of Chimonas and Hines that the curvature of the path of totality should tend to focus the waves on California.

The observers photographing the eclipse from the ground appeared to have benefited from unusually favourable conditions, which to begin with should lead to a better understanding of the solar corona. But the eclipse was not a carnival for astronomers only. On the eclipse day a research vessel from the Texas A & M University was out in the Gulf of Mexico to see how plankton reacted to the eclipse, if at all (see page 1155).

In an account of the North American eclipse of August 7, 1869, in the first issue of *Nature*, Lockyer said that the line of totality was almost one continuous observatory from the Pacific to the Atlantic, and something like that happened again in March. On this basis it can already be said that the observations on March 7 were a success, despite the parsimony that prevented the experiments from being as ambitious as might have been anticipated. One might have expected more advantage to be taken of the enormous good fortune of the rocket facilities at Wallops Island being close to the path of totality, for example, and it is a pity that there was insufficient money to make a supersonic observatory out of the aircraft that was to have chased the Moon's shadow and given more than an hour's worth of continuous totality.

The Corona during the March 7, 1970, Eclipse



THE photograph shows the solar corona observed about thirty seconds after second contact at the "High Point" camp (16° 20′ N, 6 h 25·0 m, altitude 8,800 feet) about thirty miles south-west of San Carlos, Yautepec, Mexico, by the eclipse expedition of the High Altitude Observatory of the National Center for Atmospheric Research*. The exposure was through a radially symmetric, neutral density filter in the focal plane to compensate for the steep decline of coronal radiance with increasing distance. This allows structural features to be traced from the chromosphere out to 4·5 solar radii on the original negative.

The long dimension of the frame is east–west (geocentric) and the bright helmet streamer with a prominence at its base is in the north-east (geocentric) at a heliocentric position angle of about 50°. Other bright helmet streamers appear at heliocentric positions 98°, 159°, 194° and 250°. The bright "horn" at 292° on the west limb appears on the original negatives to be due to the superposition on the line-of-sight of two fainter streamers. The corona at this time was unusual for the presence of streamers at high latitudes and the development of straight rays over the poles. The circumstances at the time of this eclipse were unusual for the rather dark sky. Long exposure photographs, made without the radially graded filter, show the lunar maria and suggest that the sky radiance did not exceed $3 \times 10^{-10} B_{\odot}$. Table 1 lists the technical data for the photograph.

Eclipse Effects in the Ionosphere

by
H. RISHBETH
Radio and Space Research Station,
Ditton Park, Slough, Buckinghamshire

This article surveys some recent trends in the study of the ionospheric effects of solar eclipses.

UNTIL recent years the principal method of studying ionospheric eclipse phenomena was vertical incidence sounding by ionosondes, supplemented by recordings of fixed-frequency signals reflected from the ionosphere and measurements of radio-wave absorption. Early work is well documented in the record of a symposium held in 1955 (ref. 1); ref. 2 gives a more recent review. These methods are still important, but now three important new techniques are available. (*a*) Instrumented rockets can be launched at sufficiently short intervals to obtain several measurements of important parameters during the course of an eclipse. (*b*) The fortuitous passage of an artificial satellite through an eclipsed region can give useful data on the upper ionosphere. (*c*) Measurements of electron concentration, electron temperature and ion temperature can be made by the incoherent scatter technique: only a few installations exist, but by good fortune several observations of eclipses have been possible.

Modern computing methods have also made feasible the construction of good theoretical models which can be used to study the effects of various physical processes on the ionosphere.

The interpretation of eclipse phenomena in the ionosphere is often based on the continuity equation for the electron concentration $N(h,t)$, a function of height h and time t. The equation is

$$\partial N/\partial t = Eq - L(N) - \mathrm{div}(N\mathbf{V}) \qquad (1)$$

where q is the rate of production of ionization in the absence of the eclipse, and L is the rate of loss. The transport term $-\mathrm{div}(N\mathbf{V})$ expresses the effect of the drift velocity $\mathbf{V}$ of the ionization caused by diffusion, electric fields and neutral air winds. The "eclipse function" $E(h,t)$ is sometimes assumed equal to the geometrical fraction of the Sun's disk not obscured by the Moon, although as discussed later this assumption may not be justified. A particular reason for studying eclipses is that the production term Eq in equation (1) varies quite quickly in relation to ionospheric time constants, whereas the normal daily variation of q is slow (except near sunrise and sunset when the oblique incidence of the solar radiation makes detailed calculations of q very difficult).

Production and Loss in the Lower Ionosphere

In the lower ionosphere (D and E-regions) the transport term in equation (1) can usually be assumed to be unimportant, so that only information about production and loss is sought. In the D-region (below 90 km altitude) the chemistry is complicated, and the electron concentration is controlled, not only by photoionization and recombination, but also by various attachment and detachment processes that lead to the formation and destruction of negative ions. An eclipse affects both the photodetachment and photoionization rates, but not necessarily in the same way because of the different solar radiations involved. Thus a full understanding of D-region eclipse phenomena cannot be expected from measurements of electron concentration alone; other parameters—particularly fluxes of solar radiations—are needed also. Rocket observations provide a means for obtaining these data.

In the E-region, about 100–120 km, the chemistry is simpler, negative ions being scarce. Many analyses of eclipse data have been made with the aid of equation (1), but without the transport term. Usually a simple recombination law is assumed, $L(N) = \alpha N^2$; this is reasonable because the recombination coefficients α for the two chief E-region ions, NO^+ and O_2^+, are probably not very different. The lifetime of the ionization is only a few minutes, so the $N(t)$ variations respond rapidly to changes of production rate. Nevertheless the eclipse analyses have not led to accurate values of q and α. This is because, as X-ray pictures of the Sun clearly show[3], the sources of the X-ray emission responsible for most E-region ionization are unevenly distributed. Although ionospheric observations made at different sites during an eclipse have enabled localized sources to be located on the solar disk[4], nowadays more precise data are obtained by X-ray photography from rockets and satellites, which does not require an eclipse. Moreover, the interpretation of the ionospheric data is seriously affected by the residual production at totality, due to X-radiation from the uneclipsed corona[5]. Even if the eclipse function $E \simeq 0{\cdot}1$ at totality, as is probably the case, the derived values of α may be several times larger than would be obtained under the assumption $E = 0$.

Transport Processes in the F-region

In the F-region the lifetime of the ionization is comparable to the duration of the eclipse, and the production, loss and transport terms in equation (1) may all be of comparable importance. Above about 250 km the loss term takes the form $L(N) = \beta N$, with β decreasing upwards. It has been shown that the height-dependent loss coefficient can account for the appearance of an extra stratification, the so-called "eclipse F1½ layer", during some eclipses[5,6]. Recent calculations, however, suggest that drift motions also play an important part in the formation of the F1½ layer[7].

Eclipse effects in the F2 layer are complex, but recently they have been used to give information on transport processes, notably in the equatorial F2 layer which is strongly influenced by drift due to electric fields[8,9]. An observation of the drift motion was made during the November 1966 eclipse at Jicamarca, Peru, using the incoherent scatter technique (Peterson *et al.*, unpublished). The eclipse "punched a hole" in the lower F-region (200–250 km altitude) at about 0800 local time; the "hole" was observed to drift upwards at a speed of 50 m s^{-1}, reaching 600 km at about 1000 local time. This is roughly twice the upward drift speed observed on a normal morning at Jicamarca, as deduced from the Doppler shift of the incoherent scatter signal[10], so it is necessary to investigate whether the drift velocity would be influenced by the eclipse. This might happen if the eclipse disturbed the distribution of electrical conductivity in the E-region, where the electric field originates. It was indeed reported that E-region electric currents (detected by their magnetic effects at ground level) did change during this eclipse[11].

Skinner[12] has analysed Nigerian F2-layer data for the October 1959 eclipse by a method that takes account of vertical drift, obtaining values of q and β that are consistent with other information. The drift velocity is found to be 5–50 m s^{-1} downward at about 1200–1400 local time. This result disagrees with the observations of upward drift at Jicamarca just mentioned, and with the contemporary theory of the equatorial F2 layer, which requires upward drift by day. Clearly, further observations are required, and it would be interesting to apply Skinner's technique to extract drift velocities from a theoretical model in which a known upward drift is incorporated.

Sterling and Hanson[7] have made calculations with a theoretical model of the equatorial F2 layer, which incorporates upward drift as well as production, loss and diffusion. They analyse their theoretical eclipse $N(t)$ curves to recover values of q and β. If the drift is ignored in this analysis the resulting values of β are about three times too big, but if the drift is taken into account more correct values of β are obtained. In either case the analysis gives reasonably correct values of q.

F-region Temperature Changes

Increases of F2-layer electron concentration sometimes occur during eclipses. These have been attributed to thermal contraction resulting from the reduction of electron and ion temperature[13], although the temperature dependence of the loss coefficient β may be a contributory cause. Thermal contraction causes a downward displacement of the topside F2 layer, which has been observed by the Alouette I satellite[14].

The changes of F-region electron temperature are influenced by several factors, the relative importance of which may vary with latitude. An eclipse reduces the direct input of heat to the electron gas, but heat may continue to be supplied by photoelectrons produced outside the eclipsed zone and travelling along geomagnetic field lines. The rate of loss of heat to the ambient ions may change because it depends on the electron and ion concentration N. Loss of heat to the cooler lower atmosphere, by conduction in the electron gas, takes place only along magnetic field lines and therefore occurs most readily at high latitudes. Qualitatively these considerations may account for the fact that reductions of F-region electron temperature have been observed during eclipses at middle and high latitudes[13,15], whereas enhanced electron temperatures accompanied the reduction of electron concentration at Jicamarca in the November 1966 eclipse (Peterson, unpublished).

Some decrease of neutral air temperature in the F-region has been measured during an eclipse[16] and it may therefore be supposed that the eclipse will affect the neutral air winds, which also influence the F-region electron concentration. This is a topic requiring further investigation.

Summary

The chief objectives of ionospheric eclipse observations may thus be summarized as follows. (1) Investigation of the distribution of sources of ionizing radiation on the Sun, using the ionosphere as a "detector". This has now been superseded by direct ultraviolet and X-ray observations of the Sun. (2) Investigation of the production and loss processes in the ionosphere. Numerous complications arise concerning the lower ionosphere, but reasonably satisfactory results seem to be obtained from observations in the equatorial F2 layer, provided transport processes are taken into account. (3) Study of ionospheric transport processes in the ionosphere, particularly motions due to electric fields and temperature changes in the F-region, and associated changes in the neutral atmosphere. The recent developments mostly relate to these processes.

Changes in the Lower Ionosphere during the Eclipse—A Preliminary Report of the Canadian Programme

Ground-based radio investigations and four rocket launches were carried out in Canada to study the effect of the eclipse on the solar radiation and electron densities in the lower ionosphere (below about 150 km). The following four articles describe the experiments.

(I) Introduction

A SOLAR eclipse provides an opportunity to study the effects on ionization densities in the lower ionosphere as the ionizing radiations are cut off. The effect should be to cause a return toward what is normally thought of as night-time conditions during the period of the eclipse. Differences in detail between the eclipse and the sunset change might be anticipated, however. During a normal sunset, atmospheric absorption progressively attenuates the various wavelengths responsible for electron production—first the short wavelength radiation is absorbed and lastly the long wavelength radiation—whereas all radiations are cut off simultaneously during an eclipse at a more or less constant solar zenith angle. If there are active regions on the Sun (sunspots), the covering and uncovering of the spots during the course of the eclipse provide an ideal situation for studying the effects of solar X-ray radiation on the ionization content of the D-region.

The effects of eclipses on the various ionospheric layers have been studied for many years[1]. Changes in ionization densities in the lower ionosphere are shown, somewhat indirectly, by observation of the phase and amplitude changes of long waves, and the observation of the change in attenuation of short waves reflected above the D-region. These results are difficult to interpret[2] and do not seem to have added much to our knowledge of the lower ionosphere. More recently, *in situ* observations by rocket-borne experiments have been reported for four eclipses: the eclipse of July 20, 1963, in Canada[3] (the electron densities for this eclipse were measured by a Langmuir probe and are therefore suspect at heights below about 90 km); the eclipse of May 30, 1965, in New Zealand[4] (this eclipse occurred near sunrise); the eclipse of February 12, 1966, in Brazil[5] and the eclipse of May 20, 1966, in Greece[6]. The *in situ* data of Kane[4,6] can be compared with the ground-based partial reflexion data of Gregory and Manson[7] and Haug *et al.* (private communication—the data are reproduced in ref. 8) obtained at nearby sites. A comparison of the time variation of electron density at 74 km during the May 20, 1966, solar eclipse in Greece, measured by the ground-based partial reflexion method and by the rocket-borne radio wave propagation method, shows reasonable agreement between the data, and a marked decrease by approximately a factor of seven, roughly centred on the visible eclipse. Several experiments were conducted during the eclipses in Greece and Brazil, but few results have been published, and except for the analysis of Kane[6] for the May 1966 eclipse in Greece, a detailed interpretation of the ionization changes has not yet appeared in the literature. The limitations of the ground-based data and the transitory nature of the rocket data are such that the maximum of the eclipse effect, and the time at which the maximum effect occurred with respect to the visible solar eclipse, are not very well established.

The eclipse of March 7, 1970, provided the opportunity of obtaining detailed data concerning the changes of electron density in the lower ionosphere using the somewhat sophisticated two-frequency differential absorption-partial reflexion systems at Ottawa[9]. Because the eclipse at Ottawa was not total (77·8 per cent at 80 km), the observations were supplemented by obtaining partial reflexion data, but with a lower performance system, at a location on the east coast of Canada, in Nova Scotia, where the eclipse was total. The observations in Nova Scotia were supplemented by *in situ* rocket measurements.

A temporary launch site was set up near East Quoddy, N.S. (44° 54·4′ N, 62° 20·1′ W). The geographic (and magnetic) latitude of the launch site is similar to that for Ottawa. A partial reflexion sounder using a four-dipole antenna system was installed at the launch site.

The rockets were launched at an azimuth of 146°, perpendicular to the eclipse track, at an elevation angle of 85°. Apogee, about 150 km, was near the centre of the midpath of the eclipse track at this altitude. Four Black Brant III rockets were launched: the first (rocket AAF-III-42) just before first contact, at 13:40:41 AST; the second (AAF-III-43) at 14:55:41 AST, so that the vehicle would be in the eclipse shadow from ground to apogee (Fig. 1): and the third and fourth (AAF-III-44 and AAF-III-45) two and eight minutes after the launch of the second rocket. The particular launch sequence was chosen because observations during previous eclipses by long wave propagation (unpublished work of Belrose) have shown that the most rapid changes occur near totality, and that the maximum of the eclipse effect is delayed after the maximum of the visible eclipse by six minutes.

The rocket-borne experiments were designed to measure simultaneously electron and ion density, by a propagation experiment and by Langmuir probes, and the intensity of pertinent ionizing radiations, by measuring the intensity of atmospheric absorption of solar X-radiation (1·5–8 Å) and of Lyman alpha radiation. The ground-based partial reflexion experiments provide (1) control day data to establish that the eclipse day was normal or otherwise, (2) data on the regular diurnal change so that this can be allowed for in establishing the change associated with the eclipse, and (3) a detailed measure of ionization changes throughout the eclipse for comparison with the transitory data obtained by rocket-borne experiments.

This research was supported by the Space Research Facilities Branch of the National Research Council and by our individual institutions. We thank many col-

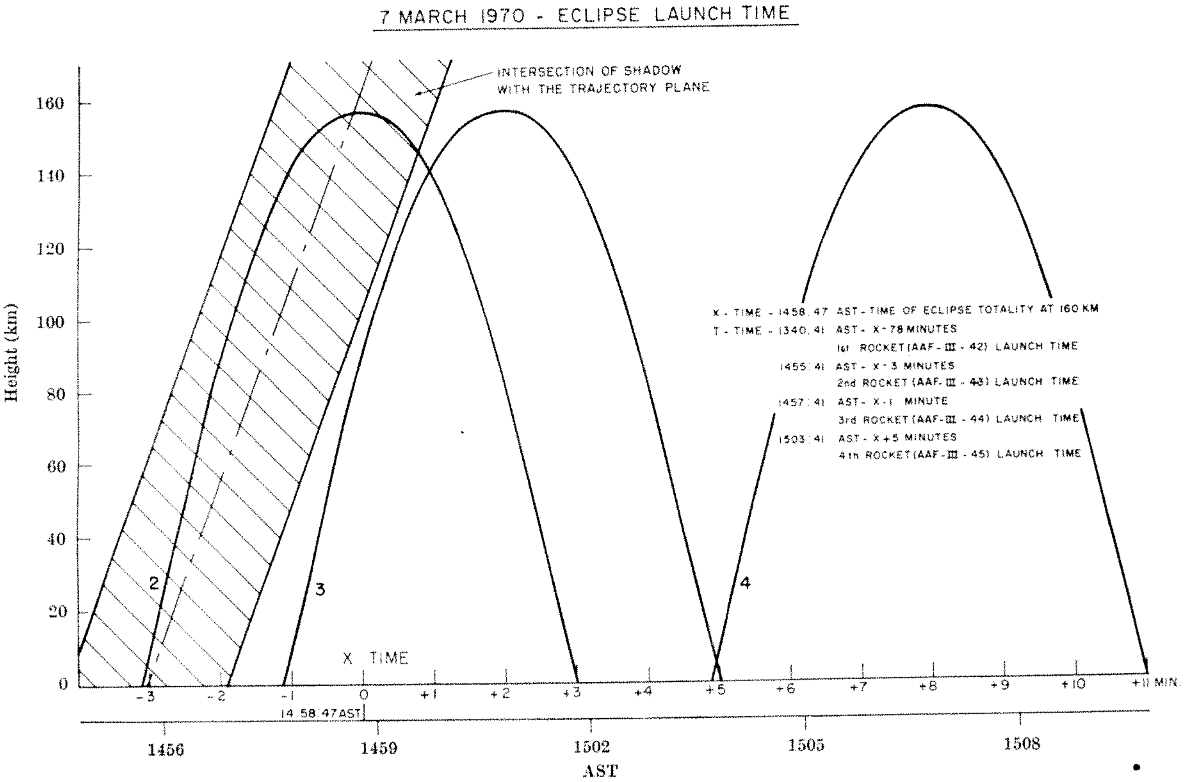

Fig. 1. Predicted trajectories with actual rocket launch times for the three rockets launched near totality. The shaded area is the intersection of the shadow with the trajectory plane.

leagues in the participating groups for help. The success of the eclipse rocket launches was made possible by the outstanding contribution of many; in particular Bristol Aerospace Ltd, in Winnipeg, the Department of Transport Meteorological Services, and the Department of National Defence Maritime Command and the Department of Transport Marine Services who provided range surveillance.

(2) Radio Propagation Experiments

GROUND-BASED and rocket-borne radio wave propagation experiments were used to study ionization changes during the solar eclipse of March 7, 1970, and the diurnal variations on control days. The eclipse path passed along the eastern coasts of the United States, and Nova Scotia and Newfoundland in Canada. The path of totality was only some 140 km wide, but a large part of the United States and Canada was partially eclipsed, and the visible eclipse in the mesosphere (at 80 km) over Ottawa was 77·8 per cent.

Observations on eclipse day, and on control days before and after the eclipse, were made by the partial reflexion method at East Quoddy (where the eclipse was total) and at Ottawa, Ontario. The observations at East Quoddy were for a 10-day period centred on the eclipse day and restricted (primarily) to the same times of day as when the eclipse occurred on the eclipse day. Observations at Ottawa were from dawn until dusk on each day, from November (as part of our studies of the winter variability) to March 1969/70.

The rocket-borne propagation experiment consisted of reception in the vehicle of the 2·66 MHz circularly polarized pulsed transmissions from the ground-based partial reflexion sounder. The receiver output provides a measure of attenuation of each of the two magnetoionic components, and hence an instantaneous measure, independent of rocket aspect and spin, of the differential attenuation.

So far the partial reflexion data at Ottawa (at both 2·66 and 6·275 MHz) and at East Quoddy at 2·66 MHz have been analysed, and preliminary electron densities for all four rocket flights have been determined. The partial reflexion data at East Quoddy were contaminated to some extent by radio interference (a marine radio telephone frequency, rather close to the operating frequency, was intermittently in use at the time of the eclipse), but portions of the data over the period of the eclipse are quite good. The rocket propagation data have been scaled from paper chart records made at the launch site, and analysis of data reproduced more accurately in the laboratory from magnetic tape recordings is currently in progress. This letter presents some of the Ottawa data, and discusses the first-look results obtained at East Quoddy.

The chief features of the partial reflexion experiment have been described already[1,2]. A high power (100 kW) pulsed MF or HF radio wave is used to probe the ionosphere. The installations used for the eclipse observations are described in Table 1.

Table 1. STATIONS USED IN THE PARTIAL REFLEXION EXPERIMENT

Location	Frequency (MHz)	Transmitter power (kW)	Antenna	Beam width	Approx. beam power (MW)
Ottawa	2·66	350	40-dipole	28°	70
Ottawa	6·275	100	128-dipole	14°	72
East Quoddy	2·66	100	4-dipole	50°	1·6

Alternate left- and right-handed circularly polarized waves (O- and X-modes) are transmitted in quick succession every second, and the weak partial reflexions from the D-region are received on a circularly polarized antenna

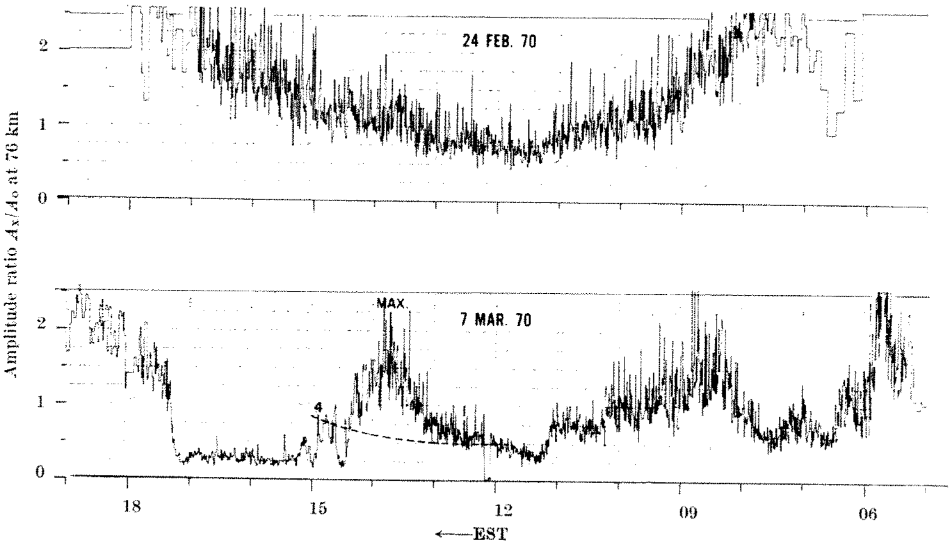

Fig. 1. Ratio-meter record (the A_X/A_0 ratio at 76 km) at Ottawa at 2·66 MHz for an undisturbed day (February 24, 1970) and for the eclipse day (March 7, 1970). The dashed line in the lower record is intended to represent the background level in the absence of the eclipse.

system, and amplified by a sensitive receiver. The basic experimental parameter is the relative amplitude of the O- and X-mode backscattered from the D-region measured as a function of height. The analogue voltage (height against amplitude echo envelope) at the output of the receiver is converted into a digital form and a digital value for each height interval of 2 km in a height range of 40 km is stored in a memory. This is done for both O- and X-mode waves. The information is then recorded on an incremental magnetic tape recorder, in a format compatible to computer analysis.

The rate of change of A_X/A_O with height, say in a 2 km interval, is a function of the change in differential absorption of the wave over that height interval, and thus, providing the collision frequency is known, the electron density can be determined. The collision frequency is determined from a measure of A_X/A_O at heights where differential absorption is negligible, and these values are extrapolated to higher heights using an assumed scale-height for the atmosphere. The A_X/A_O ratio at a particular height is inversely proportional to the electron density below that height, and is a very useful absorption parameter to study diurnal and interdiurnal changes. The ratio at a particular height can of course be determined after analysis of the recorded data on magnetic tape, but there was an urgent need to provide a record of this ratio which could be viewed and recorded in real time. Such a record could be used as a guide to inform the operator of the partial reflexion experiment when an ionospheric disturbance occurred; or in synoptic studies, because the prime data are recorded on magnetic tape, a ratio-meter record provides an invaluable aid to the subsequent more detailed analysis by computer. A digital value for each 2 km height is available in the memory each second, and so in principle it was possible to obtain the ratios of these binary numbers. There is considerable scatter in the instantaneous ratio[3], so the instantaneous values must be averaged in some way. The method developed (Ohno, private communication) involves the averaging of ten ratios, for which signal-to-noise was adequate, and of converting this value to an analogue voltage which is applied to a milliampere pen recorder. The pen recorder is held at this level until another ten good ratios have been recorded. Records obtained in this way at Ottawa are reproduced in Fig. 1.

The 2·66 MHz circularly polarized pulsed signals from the partial reflexion sounder at the East Quoddy launch site were monitored by a pulse receiver in the rocket. Pulses 50 μs long, at a rate of 20 s^{-1}, were transmitted with alternate left- and right-hand circular polarization (designated as O-mode and X-mode respectively). Positive identification was established by a differential in the spacing between pulses. The received amplitudes of each individual pulse were telemetered to the ground after logarithmic compression to a dynamic range of 40 dB. The pulses after peak detection were stretched to 5 ms so that they could be transmitted over a 200 Hz subcarrier channel of the telemetry, and in doing so the receiver was effectively gated off for this period; that is only the direct pulses and not the ionospheric reflected pulses were received.

The receiving antenna was a small ferrite loop mounted near the tip of the rocket and exposed after deployment of the nose cone. Rocket aspect and spin were not important, provided the rocket axis was approximately vertical, because even if there were spin modulation on the O- and X-wave amplitudes, the instantaneous amplitude ratio is not affected.

Solar activity increased and decreased regularly between November and February 1969/70; the 27-day periodicity in solar activity was pronounced. The 10 cm solar noise flux was a minimum on October 14–17, November 4–12, December 8–11, 1969, and January 6–9 and February 3–6, 1970. It was anticipated that there would be a minimum in solar activity just before the eclipse day, centred on approximately March 5. The 27-day periodicity, however, disappeared about the middle of February, and the Sun was very active, producing many solar X-ray (SXR) flares during the 10-day period before the eclipse, and a large geomagnetic storm ($A_p = 149$) occurred on March 8, 1970. Magnetic activity for several months before this date was very low ($A_p < 30$ during January and February). The direct and after-effects of this geomagnetic storm lasted for a week or more following March 8.

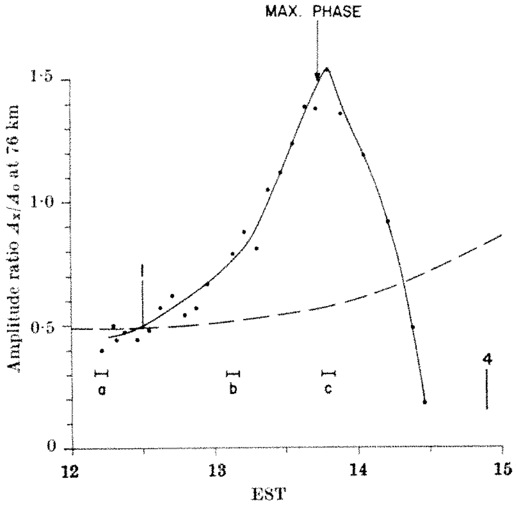

Fig. 2. Smoothed $(A_X/A_O)_{76\ \mathrm{km}}$ curve showing the solar eclipse effect observed at Ottawa at 2·66 MHz. The curve is drawn through the points averaged by computer in time intervals of five minutes, from the data recorded on magnetic tape.

The effects of these solar-terrestrial disturbances are well revealed by the ratio-meter records $(A_X/A_O)_{76\ \mathrm{km}}$. The periods of solar activity and the geomagnetic storm after-effects make it difficult to establish the regular variation for the period of one week before and one week after the eclipse, as well as the background on the eclipse day itself. The earliest date before the eclipse on which the regular diurnal variation can be observed in the absence of disturbance is February 24/25, 1970. The ratio-meter record for February 24 is shown in Fig. 1 (top). There is a clear diurnal change with the minimum ratio (that is, the maximum in electron density below 76 km) near local noon. Fig. 1 also shows the contrasting irregularity of the record for March 7, 1970. There was a marked disturbance (decrease in ratio) from 06–08 EST, which is probably a high energy particle (HEP) event; there was an SXR flare effect between 1106 and 1200 EST; and another and larger HEP event started abruptly at 1420 between the maximum phase of the visible eclipse and fourth contact. This latter event lasted until 1720 EST—what looks like a disappearance of the disturbance between 435–1510 EST is due to oblique reflexions. This is evident on examination of the A_X/A_O versus height data.

The background ionization, against which the eclipse effect is measured, is therefore rather difficult to establish. The dashed curve, in the lower record of Fig. 1, is intended to represent the variation that might have occurred in the absence of the eclipse. This curve has been fitted to the A_X/A_O values in the period just before first contact, and is extrapolated assuming a direct dependence on cos χ, where χ is the solar zenith angle. The dependence of the ratio on cos χ was established from observations on relatively undisturbed days before the eclipse.

The record of the ratio-meter is rather ragged as the trace is the average of only ten amplitude ratios. The curve in Fig. 2 shows a smoothed version of the ratio $(A_X/A_O)_{76\ \mathrm{km}}$ drawn through points averaged in time intervals of five minutes from the data recorded on magnetic tape. This curve shows quite clearly, as anticipated from LF propagation observations during previous eclipses, that the maximum of the eclipse effect was delayed (by about four minutes) after the maximum of the visible eclipse.

The partial reflexion observations at the rocket launch site near East Quoddy showed a very similar effect. The maximum of the effect was clearly delayed after totality, but the details of the curve for just before second contact cannot be established with any certainty due to radio interference from a nearby marine radio telephone channel.

The radio propagation experiment yielded good data on all four rocket launches. The first rocket was launched just before first contact when the solar zenith angle $\chi \approx 50 \cdot 4^\circ$. Differential absorption of the two magnetoionic components of the 2·66 MHz radio wave began at about 71 km altitude on this flight. The second rocket was launched during totality ($\chi \approx 61^\circ$) and the third and fourth rockets were launched two and eight minutes after the launch of the second rocket. On the three flights near totality differential absorption began at about 80 km. On the first flight the extraordinary (χ) wave was totally absorbed at about 86 km, and on the other flights near 102 km. The ordinary (O) wave was totally absorbed above 99 km on the first flight but continued to be received throughout the other three flights.

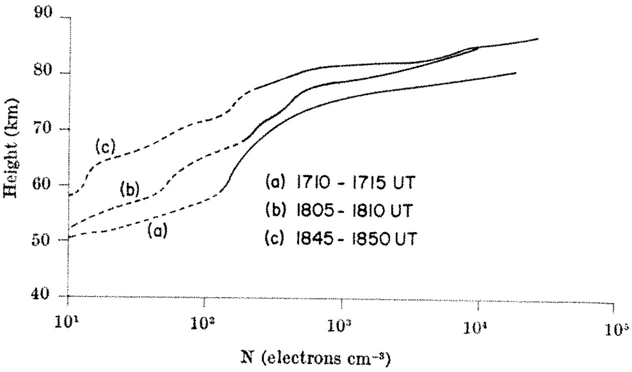

Fig. 3. Curves of electron density against height for Ottawa as determined by the two-frequency partial reflexion experiments showing the effect of the solar eclipse. The times for the various curves (labelled (*a*), (*b*) and (*c*)) are marked in Fig. 2.

The differential absorption partial reflexion data at Ottawa for both 2·66 and 6·275 MHz were analysed to yield height profiles of electron density at intervals of five minutes during the eclipse. Fig. 3 shows the profiles for 1710–1715 UT (EST plus 5 hours) which was just prior to first contact, for 1805–1810 UT when the visible eclipse obscuration was about 37 per cent, and for the time period centred on the maximum of the eclipse effect, 1845–1850 UT. Maximum obscuration over Ottawa at 80 km was 77·8 per cent. The profiles are labelled (*a*), (*b*) and (*c*), and the corresponding periods in time are indicated on Fig. 2. The continuous portions of the curves are based on the measurement of differential absorption at both frequencies, and the dashed extension to low heights is based on the assumption that in the height region where differential absorption is negligible the electron density is proportional to the O-wave amplitude[1].

Fig. 3 shows that there was a clear decrease in the electron density at all heights, the magnitude of which increased with decrease in height. The ionization densities at 80, 70 and 60 km changed approximately by factors of 2·5, 5 and 10 respectively. The results are much less reliable at the lower heights because of the extrapolation already mentioned.

The partial reflexion and rocket transmission data obtained at the launch site near East Quoddy have been analysed in a preliminary way to determine electron densities. The conclusions that can be drawn at present are as follows. The electron densities measured by the ground-based partial reflexion method and by the rocket transmission method are in reasonable agreement and indicate, as would be expected, a larger change than observed over Ottawa. The electron density at 80 km, for example, decreased by about a factor of 7. This can be contrasted with the total solar eclipse results of Kane[4], for the May 20, 1966, eclipse in Greece, which showed that the electron densities at heights of 85, 80 and 75 km changed by factors of about 7, 7·7 and 20.

(3) Probe Experiments

Three Langmuir probes for the direct measurement of charge densities[1] were mounted on each rocket, at the forward end of the payload. These were protected by a split nose cone shroud which was released at 43 s into the flight, corresponding to an altitude of about 57 km. Probe No. 1 was mounted on the vehicle axis at the foremost tip of the payload. Probes No. 2 and No. 3 were mounted on arms 33 cm long which swung outward when the shrouds were released (Fig. 1). Probes No. 1 and No. 3 were spheres 0·635 cm in diameter, and probe No. 2 was 6·35 cm in diameter. All spheres were rhodium plated. With the exception of the fins, the entire rocket surface was clean metal to provide the maximum area for the return path of the current collected by the bipolar probe systems. A sufficiently large ratio of rocket body area to probe area is required to prevent distortion of the probe-to-plasma voltage sweep, and to prevent interaction of the probes through perturbation of their reference potential. These rockets yielded an area ratio of 30,000 for the small probes and 300 for the large probe. The effectiveness of the area ratio was checked in flight by searching for interaction of the asynchronous sweeps in the current characteristics of the probes. No interaction was detected in the flight records.

Two separate and asynchronous voltage sweeps were used; one was applied to probe No. 1 and the other was applied in common to probes No. 2 and No. 3. These waveforms are shown in Fig. 1. The sweeps contained intervals of constant potential for the examination of the time variation of positive ions and electrons, and a linear sweep interval for the examination of the behaviour of the accelerating and retarding potential. The dual asynchronous sweep system and the multiple probes had the following assets: continuous recording of the spatial variation by at least one probe at any time, greater dynamic range of current collection, examination of the effect of probe size and a resulting increase of confidence in the calculated densities, and a direct check on the effectiveness of the bipolar probe area ratio in maintaining a stable reference potential.

The sweep rate, sweep cycle period, and the rocket roll rate were selected to obtain adequate height resolution, to minimize the effect of roll modulation, and to keep the signal variations within the capability of the telemetry

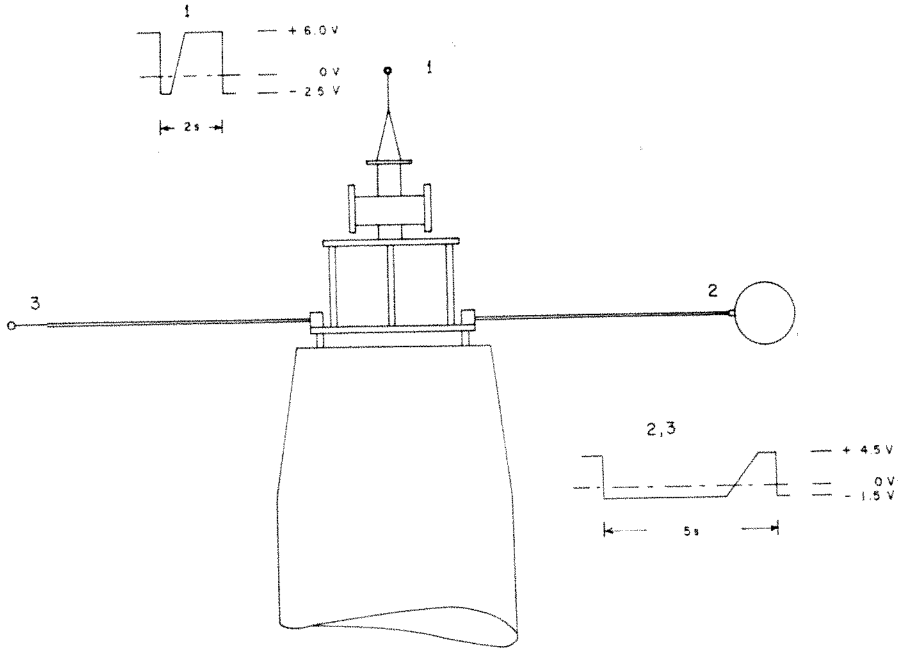

Fig. 1. In-flight configuration of the Langmuir probes. AAF-III-42/45.

bandwidth. The periods of the sweep cycles were 2·0 and 6·0 s respectively.

In addition to the Langmuir probes, a simple phototransistor photometer looking sideways was flown to monitor the visible light illuminating the rocket. This experiment also provided backup and auxiliary information for the much more accurate optical aspect sensing experiment described in the following paper.

Magnetic aspect was obtained from a three-component magnetometer system included in the payload.

The rockets were spun up to 8 Hz to obtain good stability, and then were despun at 36 s after launch to a planned roll rate of 0·6 Hz. The final roll rate was chosen to match the design values of the experiments.

Of the twelve Langmuir probes flown on the four rockets, all operated successfully except for the 6·35 cm sphere on the first rocket, AAF-III-42. This probe broke early in the flight and no data were obtained from it, but data from the other two probes on this rocket were good. The despin mechanism on this rocket failed to operate properly and the final roll rate was 1·4 Hz. This roll rate was within the tolerances of the experiments, however, and no degradation of the data occurred.

Complete reduction of the probe characteristics to charge densities has not been made yet, but plots of the currents collected by the probes give a good indication of the general behaviour of the ionization. Data were obtained from probe deployment at about 57 km to apogee at approximately 150 km. In all flights, a distinct peak in the E-region at 106 km altitude was observed. The peak electron densities during the pre-eclipse launch of AAF-III-42 at 1341 AST were typically about three times greater than those during the period around totality. Significant and rapid changes were observed in the ionization profile during the rapid sequence of launches around totality. Further details must await the complete scaling and reduction of the data from all the probes.

(4) Observations of Solar Ionizing Radiations during the Eclipse

The intensity of solar radiation at the Lyman-α wavelength, 121·6 nm (1216 Å), and in the part of the X-ray spectrum from 0·15 nm to 0·8 nm (1·5–8 Å) was measured immediately before and during the solar eclipse by experiments carried on the four Canadian Black Brant III rockets launched from East Quoddy, Nova Scotia. The purpose of the experiments was to provide data on the change in the production rate of ionization in the D-region of the ionosphere during the eclipse, so that it can be related to the change in the distribution of ionization measured by other experiments in the same payload. The first rocket was launched just before first contact, the second at totality and the third and fourth at two and eight minutes later. The trajectory of flight 2 combined with the movement of the eclipse kept the rocket in the umbra from launch until apogee. The eclipse was partial during the second half of the flight and during the whole of flights 3 and 4.

The Lyman-α sensor was an ionization chamber of coaxial construction with an end window. An effective wavelength bandpass was formed by the transmission cut-off of the lithium fluoride window and the ionization potential of the nitric oxide gas filling. The sensor was triaxially connected to a current amplifier through a −45 V supply on the central electrode. To minimize leakage current the guard electrode was also biased to −45 V. The amplifier produced a five volt output for a 20 nA input current. Three cascaded amplifier stages increased the overall sensitivity to about 20 pA.

The X-ray experiment was contained within two packages; one housed the proportional counter detector and the stabilized bias supply and the other the amplifier, pulse handling and counting circuits. The detector, which was designed by Leicester University, was of pill-box shape with a diametric anode wire and a 4 cm^2 window of beryllium, 0·013 cm thick. A collimator restricted the transverse angular response to ±30°. Operated at a bias level of 1600 V the counter had a gas gain of about 2×10^4. The spectral range of the counter was set by the thickness of the window and the pressure of the krypton filling. X-ray photons which stopped in the counter each produced

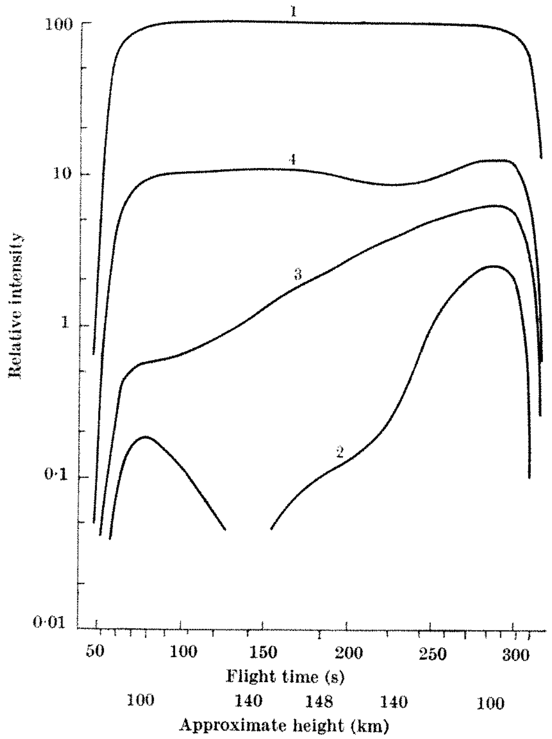

Fig. 1. **Solar Lyman-α intensity normalized to the full Sun intensity observed at apogee on flight 1. Curve 1, the intensity observed by flight 1 launched 75 min before totality; curve 2, the intensity observed by flight 2 launched at totality; curve 3, the intensity observed by flight 3 launched 2 min after totality; curve 4, the intensity observed by flight 4 launched 8 min after totality.**

a charge pulse with amplitude proportional to the energy of the incident photon. These pulses were amplified to form proportional voltage pulses. A series of voltage comparators and gating circuits were used to sort the pulses into seven intervals corresponding to predetermined wavelength ranges.

The intensity, I, of Lyman-α radiation is related to the current produced in an ionization chamber by

$I = 1{\cdot}025\times10^5\dfrac{i}{\eta A(\theta)}$ (J m^{-2} s^{-1}) where i is the chamber current in amps, η is the chamber efficiency (ion pairs per normally incident photon), $A(0)$ is the effective window area (m^2), and θ is the angle of incidence. The rockets were spin stabilized and the window faced the Sun approximately once per second. Fig. 1 shows the observed peak Lyman-α intensity as a function of flight time for the four rockets. An approximate height scale is shown which is reasonably accurate for the uplegs of the flights. The curves have been normalized to the intensity of the full Sun at the time of apogee of flight 1. Curve 1 from 50 to 80 s shows an increase in intensity as the first rocket ascended into the less dense atmosphere. This variation can be used to determine the molecular density of oxygen in the mesosphere using laboratory values of absorption coefficient. Over the central part of the flight, the intensity was essentially constant because atmospheric absorption of Lyman-α is negligible above 100 km. After 280 s absorption became significant again and the Lyman-α intensity decreased. During the first half of flight 2, while the rocket was in total shadow, the intensity never rose above 0·2 per cent of the full Sun value. This is a significant signal, however, and must have come from outside the disk of the Sun, but this does not necessarily mean that there were any sources of Lyman-α outside the disk because hydrogen in the outer atmosphere of the Sun could have scattered the radiation. The second half of flight 2 showed an increase in Lyman-α as the rim of the Sun appeared. Apart from atmospheric absorption effects, the intensity increased monotonically throughout flight 3 as more of the Sun became uncovered. The last flight showed that the intensity had recovered to about 12 per cent of the full Sun value at ten minutes after totality. Neither these nor the X-ray results have been corrected for any departure of the rocket attitude from the expected behaviour, but no large corrections are anticipated.

At times when the sensors were facing away from the Sun due to rocket spin, the Lyman-α intensity did not fall to zero. Fig. 2 shows the background intensity observed during flights 1 and 3. The background intensities measured on flights 2, 3 and 4 were similar and about a third of that measured on flight 1. Unlike the signals from the Sun the background Lyman-α continued to increase in intensity up to the apogee of the trajectory. This is probably because the background, due to resonant scattering of Lyman-α by hydrogen in the Earth's atmosphere, entered the sensor from a large range of zenith angles. The relatively small difference between the full Sun and eclipse backgrounds supports this view because, in the latter case, scattering must have been from distant parts of the Earth's atmosphere still strongly illuminated by the Sun.

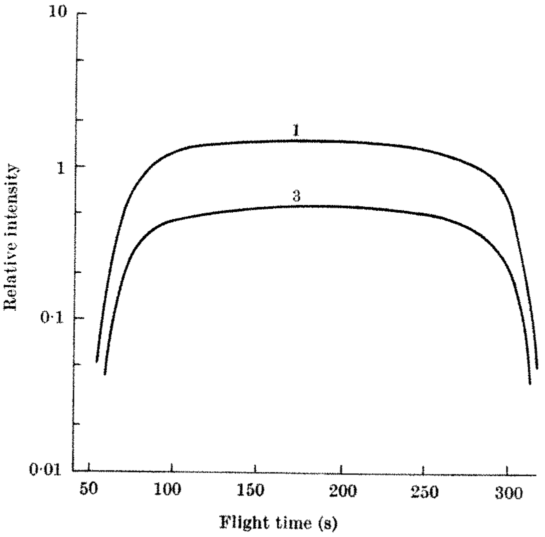

Fig. 2. Background Lyman-α intensity normalized to full Sun intensity. Curve 1, background intensity observed on flight 1; curve 3, background intensity observed on flight 3.

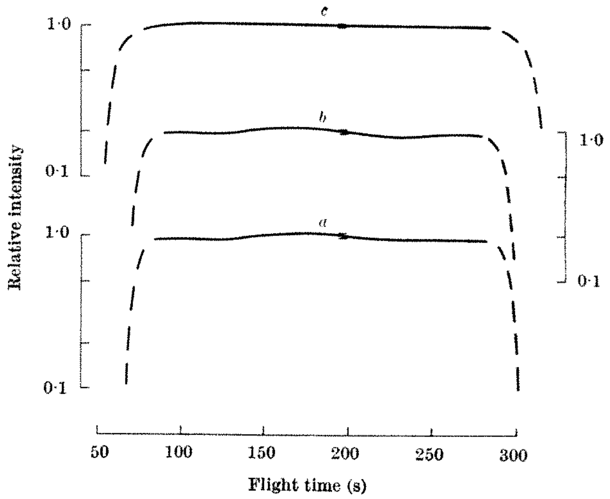

Fig. 3. Comparison of normalized X-ray (*a*, 0·25 nm; *b*, 0·6 nm) and Lyman-α (*c*) profiles, flight 1 (full Sun).

The X-ray photon count was recorded in seven channels covering energies corresponding to wavelengths from 0·15 nm to 0·8 nm. Only the data from channels 2 and 6 which centred on approximately 0·6 nm and 0·25 nm repectively will be considered here.

As the rocket rotated on its axis, the X-ray sensor faced the Sun approximately once per second. The counts observed during each rotation were recorded and a small background count has been subtracted. Fig. 3 is a plot of the count rate for channels 2 and 6 observed on flight 1, each normalized to the maximum count observed during the flight, and the Lyman-α curve from Fig. 1 is shown for comparison. The parts of the curves severely affected by atmospheric absorption are shown broken.

Analogous curves for flight 2 are given in Fig. 4. The variation in the X-ray intensity in both channels is superficially similar to the Lyman-α variation, but there are differences in detail. The Lyman-α intensity increased by a factor of ten after 220 s, whereas both X-ray channels had their maximum rate of increase earlier than this, at a time when the solar disk was still covered. The differences in the shapes of the curves are significant, and the error bars indicate the random spread in the individual points, derived from the counts per rocket rotation.

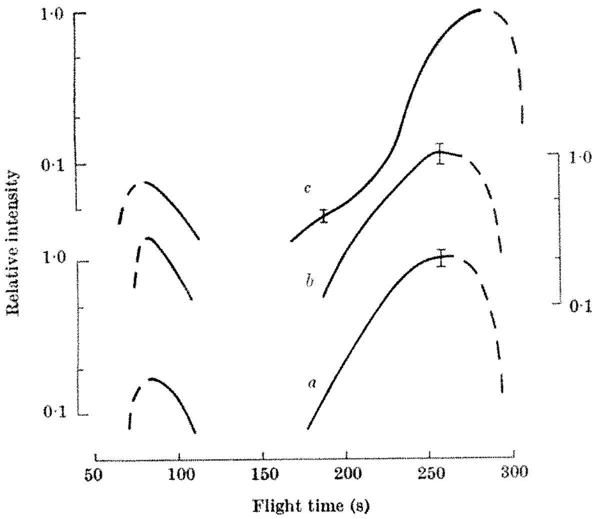

Fig. 4. Comparison of normalized X-ray (*a*, 0·25 nm; *b*, 0·6 nm) and Lyman-*α* (*c*) profiles, flight 2 (at totality).

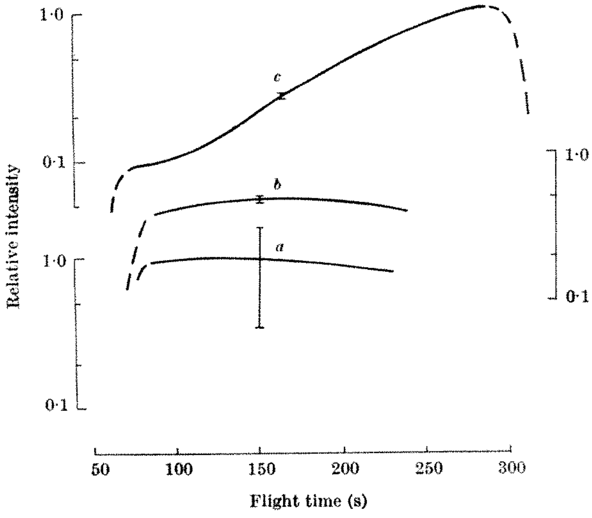

Fig. 5. Comparison of normalized X-ray (*a*, 0·25 nm; *b*, 0·6 nm) and Lyman-*α* (*c*) profiles, flight 3 (2 min after totality).

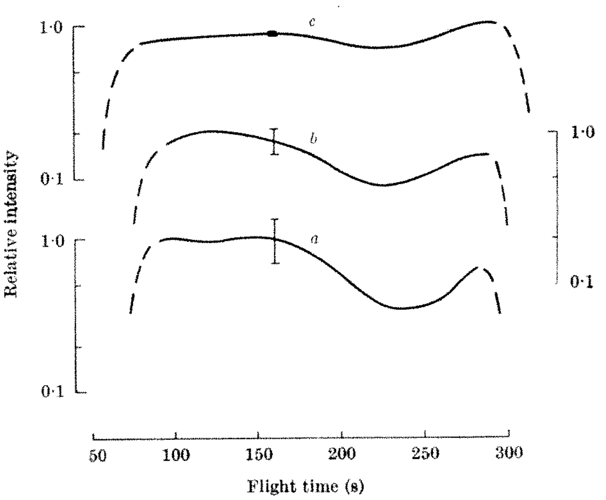

Fig. 6. Comparison of normalized X-ray (*a*, 0·25 nm; *b*, 0·6 nm) and Lyman-*α* (*c*) profiles, flight 4 (8 min after totality).

The data from flight 3 presented in Fig. 5 again show differences between the intensity variations for Lyman-α and X-rays. The former increased throughout this flight as the Sun became uncovered, whereas the latter was fairly constant, actually decreasing a little after a flat maximum near 150 s. This decrease is not too difficult to explain because X-rays usually originate in a few small regions of the Sun but the source of Lyman-α is from much larger and more widely distributed patches. Although the area of uncovered Sun increased through the flight, the orientation of the exposed crescent changed due to the motion of the rocket, and it is quite possible for a small X-ray source to have become covered during the later part of the flight. It has not yet been possible to analyse the X-ray data for flight 3 after 240 s.

Fig. 6 shows the data for flight 4. In this case, the intensities of X-rays and Lyman-α did not change much during the flight, which means that there were no new major sources uncovered. The dip at about 230 s probably corresponds to an active region becoming partly covered and then uncovered again. The decrease was much more significant for X-rays than for Lyman-α.

The solar radiation data from these four rocket flights will be used to calculate the production of ionization in the D-region as well as to study the sizes and distribution of Lyman-α and X-ray sources on the Sun. The absorption of the radiation in the lower atmosphere will be used to find the atmospheric density. The Lyman-α intensity will be combined with data on nitric oxide concentration, obtained by other workers, to calculate the distribution of production of ionization. The data from the seven X-ray channels will be used to derive an X-ray spectrum. Combining this with the known absorption and ionization cross-sections, the production of ionization due to X-rays will be calculated and added to that due to Lyman-α. A study of the relation between variations in the production and the density of ionization during the eclipse should give information on loss rates and possibly other ionospheric parameters.

We acknowledge the parts played by our colleagues in obtaining these data, and thank the National Research Council of Canada for inviting us to take part in its eclipse programme.

Preliminary Results from a Meteorological Rocket Experiment

THERE is little question that important ionospheric changes occur during a solar eclipse. Dramatic evidence was obtained, for example, in the eclipse of November 12, 1966, when rocket measurements in Brazil showed a reduction in the electron concentration of the D-region by several orders of magnitude, symmetrical about the time of totality (unpublished report). Less secure is the evidence for changes in the neutral stratosphere and mesosphere. Large increases in the amount of total ozone deduced from ground observations are at variance with the increases deduced theoretically by Hunt[1], who believes that neglect of limb darkening of the Sun would have influenced the past results obtained with Dobson spectrophotometers. For meteorologists the temperature of the upper stratosphere, determined initially (in the absence of circulation effects) by solar absorption by ozone in the Hartley region, is of primary importance. Temperature changes due to an eclipse and those occurring from day to night are not exactly comparable, because in the latter case there is a gradual but large variation of solar elevation angle. It is nevertheless interesting that satisfactory agreement has not been found (unpublished work of Quiroz) between observed day–night temperature changes and theoretically derived estimates of the diurnal variation[2].

The changes occurring during a total solar eclipse are of special interest because of the rapid obscuration of the Sun at a relatively constant solar elevation. Provided that the real temperature variation can be separated from instrumental and radiational error, the eclipse data may throw light on the magnitude of the radiational error and perhaps also on the real diurnal variation. The first rocket attempt[3] to find the temperature change due to an eclipse was made on November 12, 1966, at Tartagal, Argentina (23° S, 64° W). Although a detailed analysis was not published, the observational data indicated a temperature drop exceeding 10° C near 50 km, in the eclipse, and an increase of about 20° C at 60 km from before totality (1034 local time) to an observation time in mid-afternoon. Clearly some clarification of the temperature changes due to an eclipse is needed. Moreover, a large temperature variation if sustained over a deep atmospheric layer would imply a large perturbation in the pressure field, with significant effects on the circulation. Indeed, Chimonas and Hines[4] have recently suggested that measurable internal gravity waves should be induced by the cooling action of an eclipse.

An experiment with small meteorological rockets was thus carried out at Wallops Island, Virginia. (37° 50′ N,

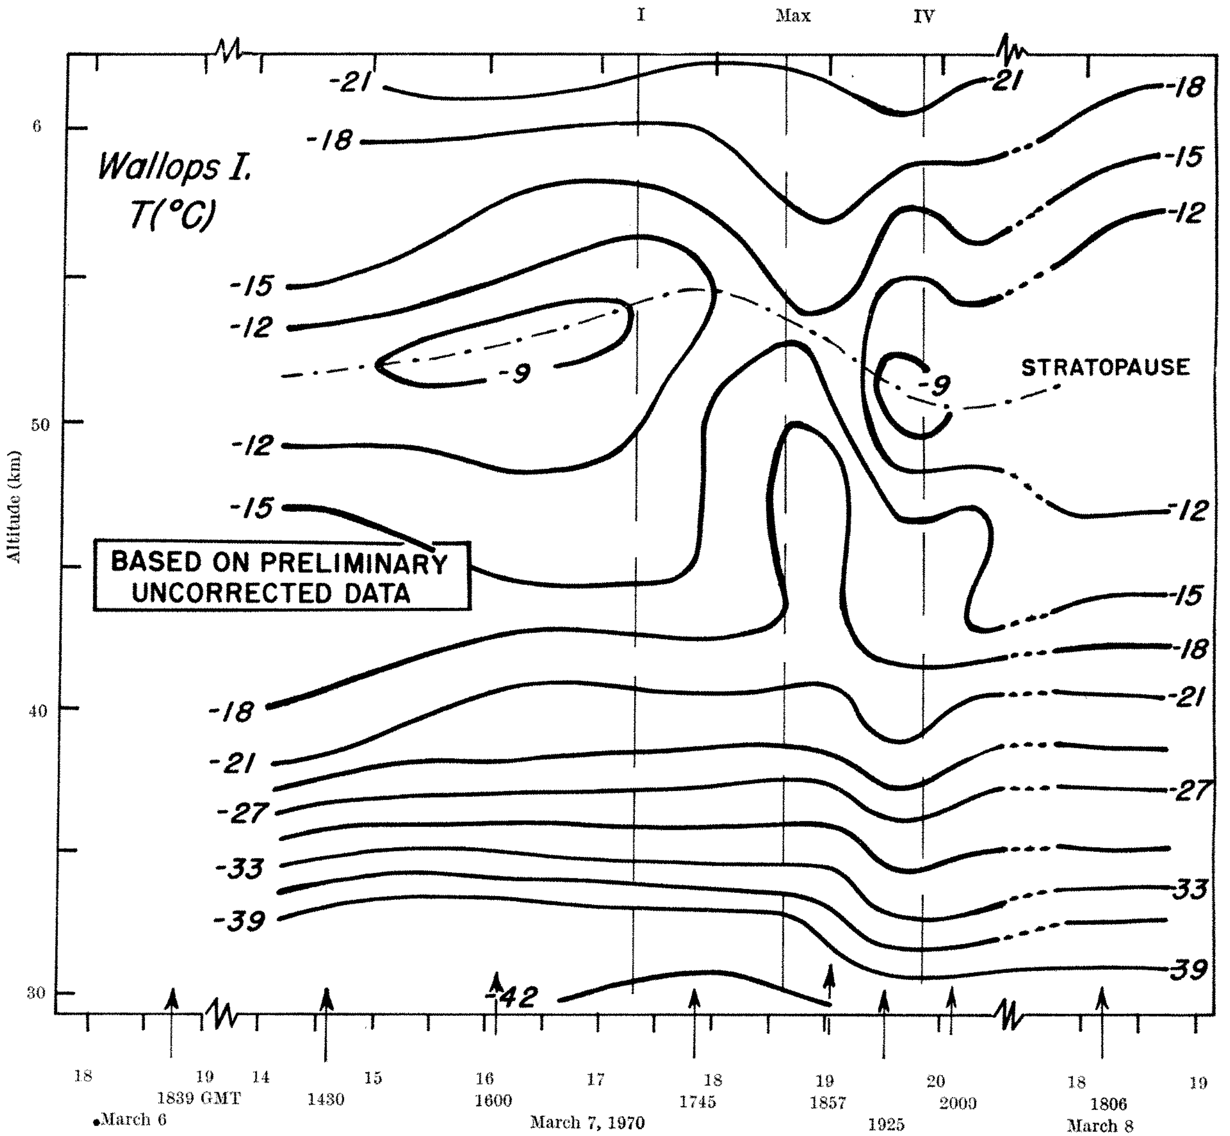

Fig. 1. Preliminary analysis of smoothed rocketsonde temperatures for Wallops Island, Virginia, for the solar eclipse of March 7, 1970 indicating a temperature decrease by as much as 7 degrees within the layer 40–60 km.

75° 29′ W), giving detailed temperature and wind data before, during, and after the eclipse of March 7, 1970. Wallops Island was ideally suited for this purpose because the expected trajectory of the sensors would place them close to the central path of the eclipse[5]. The purpose of this report is to describe the experiment and to present a preliminary analysis of the temperature results.

Table 1. ARCAS ROCKET SOUNDINGS AT WALLOPS ISLAND

Launch date	Time (GMT)	Rocket apogee (km)	Highest alt. of temp. data (km)	Sensor fall rate (m s^{-1}) 60 km	50 km	40 km

Primary tracking by FPS-16 precision radar, except for observation at 1857 (MPS-19 radar).

* Eclipse sounding.

Eight ARCAS rockets were launched at the times given in Table 1. Three of these were fired during the eclipse, which began at 1720 and ended at 1952 GMT, with maximum (complete obscuration) at 1838 GMT (1338 EST). The remaining ARCAS soundings served to establish the background meteorological conditions. From the standpoint of altitudes attained and data acquisition the experiment was eminently successful. Minor disappointments were a relatively low apogee on the day before the eclipse, and a broken thermistor in a sounding originally scheduled for 1745 GMT on March 8. The latter required the launching of a backup ARCAS rocket 21 minutes later (1806 GMT). Radar acquisition and telemetry were excellent throughout. A series of LOKI rockets, less sensitive to wind, were made ready for launching in the event of very strong low level winds, but these were not required.

Obviously it would have been desirable to fire one or two more small rockets close to the time of totality, but logistical requirements for the total complex of experiments conducted at Wallops Island on March 7 precluded this. We look forward to the review of temperatures from rocket soundings with pitot static probes by the Goddard Space Flight Center and the University of Michigan; these measurements obtained at 1759, 1826, and 1841 GMT during the eclipse are free from any radiation error and should therefore serve as a further check on our results. Our final analysis will not only take these data into account, but will also be made within the context of the pattern of ozone variation measured by NASA.

A direct analysis of the temperature data showed much small-scale detail of the type commonly found in atmospheric soundings[6]. To portray the main features, averages over 3 km overlapping by 1 km (thus yielding smoothed temperatures at 2-km intervals) were obtained. These were analysed objectively without special attention to the eclipse phase, and subsequently verticals were entered (Fig. 1) to denote the begining (I), maximum, and end (IV) of the eclipse. Arrows for observation times are 5 minutes after launch, corresponding to the time when the sensors descended to approximately the 50-km level. At this time and altitude the measurements during the eclipse were near a point 50 km (27 nautical miles) ESE of Wallops Island. At this geographical location and altitude, the obscuration of the Sun was 27, 64, and 21 per cent, respectively, 5 minutes after the eclipse launch times 1745, 1857, and 1925 GMT. For the preliminary analysis, the sounding on the day before the eclipse has been omitted until a temperature variation near 40 km, apparently of synoptic origin, is examined with the aid of data obtained earlier in the week.

Fig. 2*a* illustrates the detail present in the original data for two selected soundings and Fig. 2*b* shows the effect of smoothing the data. Note the meeting of the curves just above 60 km.

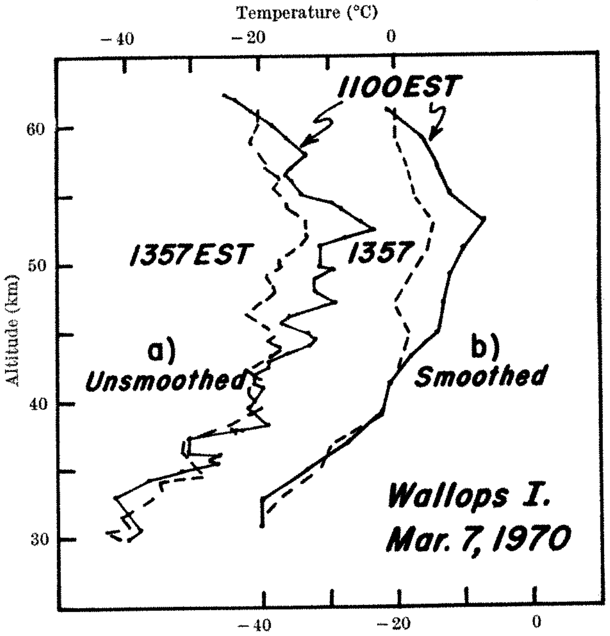

Fig. 2. Smoothed and unsmoothed temperature profiles for sounding before eclipse (1600 GMT = 1100 EST) and sounding during eclipse (1857 GMT).

In Fig. 1 the most arresting features are: (1) A perturbation in the temperature field essentially contained within the period of the eclipse, and chiefly within the layer 40–60 km. (2) Maximum amplitude 5°–7° C at 45–55 km, with minimum temperatures indicated a few minutes after totality. (3) Rapid warming just before the end of the eclipse, as indicated by the 1925 GMT observation. This effect, however, may be partly spurious. Recent comparison tests have shown good agreement between meteorological rocket soundings obtained a few minutes apart, under controlled conditions. To illustrate, the r.m.s. difference in each of several 5-minute pairs of LOKI-Datasonde temperature profiles was less than 2° C and similar results were obtained in pairs of ARCASonde profiles from rockets launched a few days before the eclipse experiment. To preclude an error contribution from the sensors, the bead thermistors were minutely examined and carefully recalibrated just before the experiment.

Under the influence of some direct radiational error and aerodynamic heating due to the fast descent of the sondes, however, the sensors give temperatures which above about 50 km may be several degrees above ambient. The radiational error has been considered small (unpublished work of Ballard), less than 3 degrees, but in any case should be examined anew according to the observational circumstances. In the present data the fact that cooling appears in a discrete layer, with relatively unchanged temperatures above as well as below, indicates that the perturbation is not due simply to radiational error, which would increase upward. Corrections for these factors will be applied by established methods to the observed temperatures (unpublished work of Lacey and Staffanson), but except for the variation imposed by the observation at 1925 GMT, the overall pattern should not be strongly affected. From Table 1 it is seen that the sensor at 1925 underwent an especially high rate of fall, so that aerodynamic heating greater than usual may partly account for the slope of the isolines around that time. For this preliminary analysis, however, the extra heating expected from the increase in fall rates from 1857 to 1925 GMT was evaluated numerically, and an adjustment was made to the curves above 50 km.

Final conclusions must await not only refinement and correction of the present data, but also comparison with other results, especially the pitot tube measurements at Wallops Island and meteorological results obtained on March 7 by experiments from White Sands Missile Range at Eglin Air Force Base, Florida, and in Mexico. An explanation of the difference in temperature results in 1966 at Tartagal and in the recent eclipse should be sought. Some of the difference may be due to the differing solar elevation at the time of maximum eclipse (about 70° at Tartagal and 40° at Wallops Island).

Wind data have not been completely processed. Pressure data derived hydrostatically from the March 7 temperatures indicate a variation in the height of the 0·4 mbar surface (the highest pressure level for which synoptic maps are now prepared) by about 300 m. Thus we may also expect to see some effect in the winds from the eclipse.

Rocket Density Measurements at Eglin, Florida

THREE falling sphere experiments instrumented with omnidirectional accelerometers were launched at Eglin, Florida, during the total eclipse of March 7, 1970. The first rocket was launched near first contact, the second near totality and the third near fourth contact.

Recent observations of neutral atmospheric density and temperature obtained with the 7-inch falling sphere rocket experiment indicate that above 60 km the short-term variations of the order of 3 to 6 h are sometimes greater than those of seasonal average values. This applies in particular to the temperature results obtained near the level of the mesopause[1,2] and to density results between 90 and 105 km (ref. 3). In fact, the amplitudes of these variations are usually large enough to preclude accurate measurement of a diurnal effect in these altitude regions. Diurnal variations of the order of 7–20 per cent have been determined, however, from 30 to about 70 km (ref. 4 and unpublished work of Thiele). On the basis of these observations it seems reasonable to speculate that only small changes in density are likely to occur under the short-term transient conditions of a total eclipse. The three *in situ* measurements of neutral density reported here were therefore intended for use primarily as an accurate reference frame for correlating measurements of total density with measurements of O_2 and O_3 from optical payloads (conducted by L. Weeks, AFCRL) launched at Eglin Gulf Test Range and other ionization and composition experiments launched from Wallops Island, Virginia.

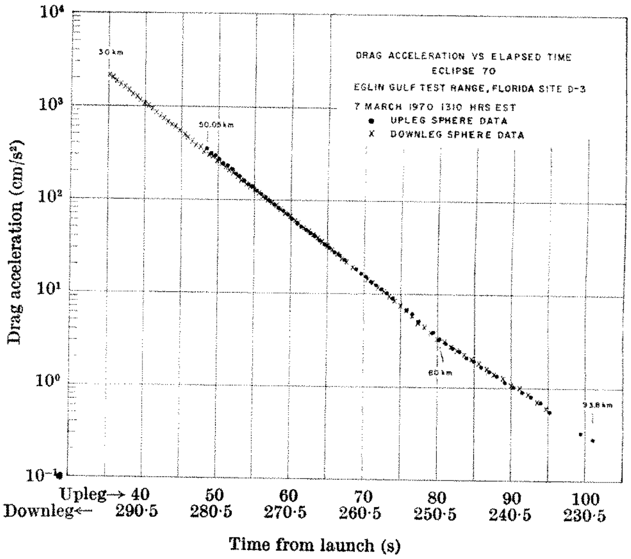

Fig. 1. Results from rocket 2 launched near totality.

Sphere trajectories and rocket sub-points (position coordinates and altitude as a function of time from launch) are being calculated at present to determine the positions of the measurements relative to the progression of the eclipse. Table 1 summarizes the launches.

The launcher azimuth settings, calculated for optimum interception with the path of the eclipse, were compromised slightly by high surface winds that prevailed during each firing. The preliminary flight results presented here consist of sphere drag acceleration data from which density profiles are determined.

The AFCRL 7 inch rigid falling sphere which determines density in the altitude range 30 to 120 km (refs. 5 and 6) was used on rockets 2 and 3 near totality and fourth contact respectively, and is instrumented with an omnidirectional accelerometer and telemetry. It is deployed from an ascending rocket at an altitude of 50 to 60 km. At payload separation the accelerometer begins to sense atmospheric drag on the sphere during its free flight. The data are telemetered to ground-based stations which record the information on magnetic tape and provide a digital print-out in real time. Temperature results are deduced from the density data. The system error is not greater than 5 per cent at the highest levels of the measurements (Murphy, unpublished).

The AFCRL 10 inch MICRO-G falling sphere, launched near first contact, was flown for the first time during this eclipse. It was instrumented with telemetry and a three axis ultrasensitive accelerometer which operates on the principle of a capacitive bridge. The voltage output from each of three orthogonal axes is approximately proportional to the displacement of a reference mass from a central or null position within a spherical cavity. The mass, which is positioned mechanically at the centre, is displaced by air drag on the exterior surface of the falling sphere. The accelerometer was developed by the Upper Air Research Laboratory of the University of Utah under an Air Force contract. Preliminary evaluation of the flight data indicates a threshold sensitivity of about

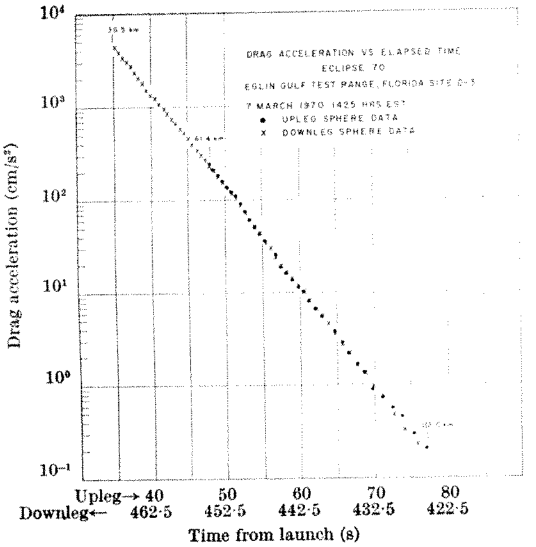

Fig. 2. Results from rocket 3 launched near fourth contact.

10^{-7} g and a useful altitude range of about 30 to 145 km when the payload is boosted by a Nike Iroquois rocket. Total drag acceleration is obtained from vectorial addition of the components of acceleration on each axis of the accelerometer.

The drag acceleration results shown in Figs. 1 and 2 were obtained from 7 inch falling spheres. Because drag acceleration is proportional to density the results presented here are useful for qualitative evaluation of the data.

The data of rocket 2 launched near totality, which attained a peak altitude of only 111 km due to a malfunction, are shown in Fig. 1. Drag accelerations obtained during ascent and descent are in excellent agreement, although the independent measurements were separated in time by approximately three minutes. Note that the downleg time scale is reversed so that both ascending and descending drag curves have similar slopes to facilitate comparison of the data. Because drag acceleration, like density, is a logarithmic function of altitude, a semilog plot of drag acceleration as a function of elapsed time (for selected intervals) should fall approximately along a straight line for a normal or undisturbed atmosphere, provided the trajectory is nearly symmetrical with peak time. The data in Fig. 1 show some structure above about 70 km which may be due to a departure from normal conditions. Because of the excellent agreement in ascent/descent data even the small perturbations observed must be considered as real changes in the thermodynamic structure of the atmosphere.

As noted in Table 1, a chemical release payload was combined with the falling sphere on rocket 2 to provide simultaneous upper atmospheric measurements. The objective of the chemical release experiment, proposed by K. S. W. Champion of AFCRL, was to measure upper atmosphere motions in the 80–150 km altitude range during the maximum phase of the eclipse. The payload consisted of sodium and lithium to be released in sequence. These chemicals were selected to obtain maximum contrast between the chemical trail and the sky background when photographed with appropriate interference filters on the cameras. Three camera sites, used to determine atmospheric motions by standard triangulation techniques, were located so as to be in darkness during totality while the chemical release trail would be partially sunlit. Unfortunately no observations were obtained due to heavy cloud cover.

The results obtained from rocket 3, launched near fourth contact, are shown in Fig. 2. These data also exhibit structure, but to a smaller degree than that observed on rocket 2. This seems consistent with the concept that data obtained at late times relative to the maximum phase of the eclipse should represent near normal atmospheric conditions.

Flight results obtained on rocket 1, launched near first contact, have been reduced partially from strip chart records. This method, although not highly accurate, provided check points which suggested near normal atmospheric conditions between 81 and 107 km altitude. A computer program is being developed to provide quantitative results for a later publication.

Our preliminary conclusion is that the drag acceleration data show more structure than had been anticipated under the short-term transient conditions of a total eclipse. The results suggest a maximum change in atmospheric structure near totality and a decreasing change near fourth contact.

I thank E. A. Murphy (AFCRL), Gustave Stromberg, Paul Mundis and associated personnel at Wentworth Institute, Boston, Massachusetts, for help and Dr K. S. W. Champion (AFCRL) for valuable discussions.

Changes in the Electron Content of the Ionosphere

The earliest ionospheric effect of a solar eclipse was noticed by Appleton during the English eclipse of 1927. He detected a four-minute time delay between the minimum in the electron density of the E-region and the time of maximum obscuration. This delay is consistent with the fact that the ionization of the upper atmosphere is caused by ultraviolet radiation rather than by particles emitted from the Sun[1]. Subsequent investigations[2] have revealed that the sources of E-region ionization are somewhat localized over the solar disk, with a significant contribution also emanating from the chromosphere. The rapid response of the E-region to an eclipse is a direct consequence of the short electron recombination times at these heights (~90 s). In the F-region of the ionosphere, however, these recombination times become large (~hours) and the observed eclipse effects are controlled by the process of plasma transport. The chief purpose of the experiment described here was to investigate this transport.

The experiment measured the Faraday rotation introduced by the ionosphere on the 137 MHz transmissions of two geostationary satellites, ATS-I and ATS-III, located respectively at 150° W and 85° W. The geographical location of our observation site at Miahuatlan in Mexico is shown in Fig. 1, which also shows the sub-ionospheric points of various heights along the signal paths to the two satellites. To an observer on the ground, the signal from each satellite is polarized elliptically with a known orientation. The total rotation Ω, in radians, incurred by the satellite signal during its passage through the ionosphere is given by

$$\Omega = 2{\cdot}36 \times 10^4\ \nu^{-2} \int_g^s \{B_0 \cos\theta \sec\chi\} N dh$$

where ν is the wave frequency, B_0 is the geomagnetic field strength, N is the electron density, h is the altitude above the ground and θ and χ are the angles which the signal propagation path makes with the magnetic field and the vertical respectively (mks units are used throughout).

The centre of gravity of the ionospheric electron density distribution is known to be at approximately 350 km. By evaluating H, θ and χ at this height, the measured Faraday rotation can be simply related to the electron contents of vertical columns passing through the sub-ionospheric points A and B shown in Fig. 1. These sub-ionospheric points are at roughly the same latitude (15° N) but are separated approximately by 6° in longitude.

Fig. 2 shows the effective total electron contents at the locations A and B on the eclipse day and on the previous control day. At both locations it is found that, relative to the control day, the electron content starts to decrease after first contact. A minimum in electron content is observed approximately at the time of maximum obscuration. But the maximum reduction of electron content occurs approximately twenty to thirty minutes later than the obscuration maximum. At 102° W (Fig. 2*A*) where the maximum obscuration was 86 per cent, this reduction amounted to $2\cdot3\times10^{17}$ electrons m^{-2}. Somewhat anomalously, the corresponding maximum reduction at 96° W (Fig. 2*B*), where the eclipse was total, was $1\cdot7\times10^{17}$ electrons m^{-2}. These values represent one quarter of the total number of electrons in the ionosphere, and are significantly larger than the reductions measured by Evans[3] and Klobuchar and Whitney[4]. Their measurements were made at high geomagnetic latitude during a period of solar minimum in the month of July.

In order to interpret our observed eclipse effects, it is important to realize that the Faraday rotation technique is primarily sensitive to the F-region and to the topside ionosphere which accounts for approximately 80 per cent of the total content. Because of the large recombination times at these heights, the observed rapid changes in electron content clearly demonstrate the importance of ionization transport. As Evans[3] has noted, such transport is promoted by the rapid decrease of the temperature of electrons (and to a lesser extent of ions) in the topside ionosphere. The transport is essentially aligned with the geomagnetic field. The extent of electron reduction observed in Fig. 2 will therefore depend upon the relative orientation of the geomagnetic field and the lines of sight to each satellite. This geometrical consideration might have some bearing on the anomaly in the maximum electron reductions shown in Fig. 2.

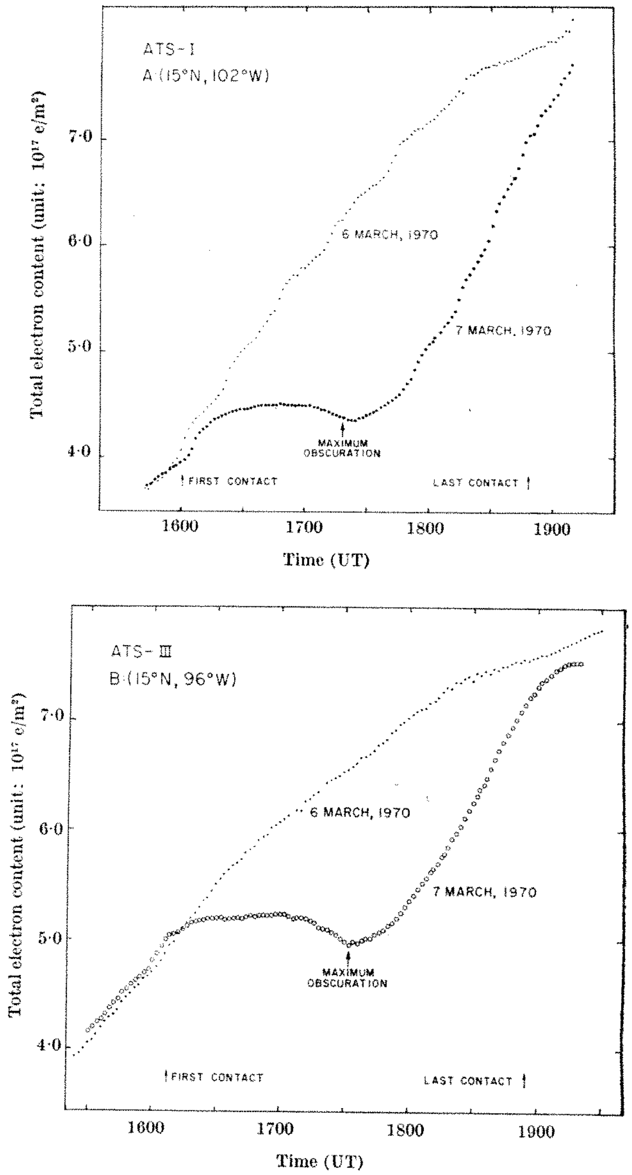

Fig. 2. The effective total electron content at the locations A and B shown in Fig. 1 for the eclipse day, March 7, 1970, and the previous control day.

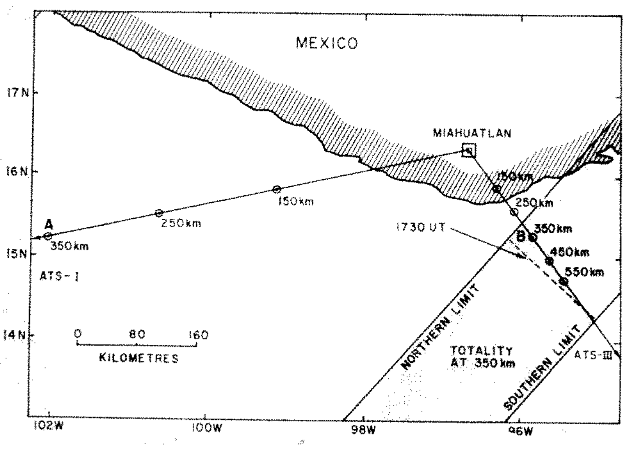

Fig. 1. The location of the observation site showing the path of totality of the eclipse at 350 km, and the lines of sight to the geostationary satellites, ATS-I and ATS-III.

A detailed analysis of our observations is being undertaken using ionosonde data from El Cerrillo near Mexico City. This should enable us to develop a model for transport of ionization in the topside ionosphere.

This work was supported by the National Science Foundation. We thank Dr A. E. Belon for his help in coordinating our experiment, Dr Arcadio Poveda and the Mexican government for making our stay in Mexico enjoyable, and P. Kuttner and F. D. Scruggs for help.

Comparison of Changes in Total Electron Content along Three Paths

THE total electron content of the ionosphere during the March 7, 1970, solar eclipse was measured along paths towards three geostationary satellites from a ground station at Hamilton, Massachusetts. The Sun was 96 per cent eclipsed at the ground at Hamilton.

The total electron content (TEC) was determined by monitoring the amount of twist of the polarization of linear, attitude stable, VHF radio waves transmitted from the geostationary satellites Early Bird, ATS-3 and ATS-5. Only the relative polarization twist from each of the three geostationary satellites was monitored, and conversion to absolute polarization twist was as follows, based on measurements of the relative polarization angles at Hamilton, Mass., from the ATS-3 satellite which have been taken on a nearly continuous basis for more than two years. The relative polarization angle is periodically put on an absolute scale by measuring TEC by the two-frequency differential Faraday method from VHF signals transmitted from one of the two S-66 satellites, BE-B and BE-C. The S-66 satellites, BE-B and BE-C, are in approximately circular orbits 1,000 km high having inclinations of 80 degrees and 41 degrees respectively. The S-66 satellites have not been transmitting continuously, and the spacing of their two transmitted frequencies still leaves ambiguities in absolute polarization twist. But it is possible to build up experience in determining absolute TEC from the continuous monitoring of signals from the geostationary satellite over a relatively long period, say at least one month, from calibration by means of S-66 passes which occur before dawn or in late evening, and by comparison with local ionosonde data. An incorrect estimate of the absolute amount of polarization twist will result in unreasonable values of equivalent slab thickness, the ratio of TEC divided by density at the peak of the F-region, particularly at night-time.

By a combination of comparison with BE-C data and f_0F_2 data from the Wallops Island ionosonde, the absolute polarization twist and, hence, the TEC along the path from the satellite ATS-3 was found. The TEC along paths from the satellites ATS-5 and Early Bird were simply scaled to the ATS-3 values at a time before the eclipse.

The amount of polarization twist is proportional to the integrated product of the electron density times the longitudinal component of magnetic field intensity. As is common practice with this type of measurement, the values of polarization twist were converted into equivalent vertical TEC by using the longitudinal magnetic field intensity and zenith angle at a mean ionospheric height—350 km in this case. The resultant equivalent vertical TEC values were then assigned to the subpoints 350 km ionospheric height. Because the longitudinal component of the magnetic field times the zenith angle changes slowly as a function of height, an error in TEC of less than 8 per cent would have been introduced along each path by choosing an unlikely high height of 500 km rather than 350 km.

Fig. 1 shows the location of the receiving station and the 350 km sub-ionospheric points along the paths to the three satellites. Also shown are the locations of the ionosondes which were operating during the eclipse, Fort Monmouth, New Jersey, and Wallops Island, Virginia, and the ground projection of the sub-ionospheric path of the eclipse shadow at a height of 300 km. The eclipse shadow at 300 km was approximately 130 km wide[1].

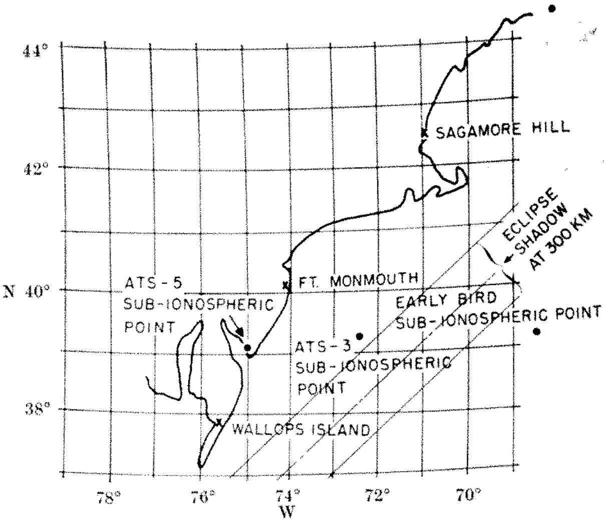

Fig. 1. Map of the area.

Fig. 2 shows the equivalent vertical TEC results during the eclipse day, along with the mean of the three days preceding the eclipse. Early Bird data were not available early on the eclipse day because the VHF transmitter was turned off for a satellite manoeuvre. The three curves for the eclipse day are nearly identical, with the exception that the recovery along the Early Bird path was not as great as along the other two paths. The path from the Early Bird satellite was furthest east, or latest in local time, and could be expected to recover least of the three paths because of the lower solar elevation angles along its path.

The maximum change in TEC from the mean of the three preceding days was approximately −30 per cent. The time delay from the time of maximum optical obscuration to the observed minima in TEC along the three paths was approximately 20 minutes. No significant differences in time delay were noted along the three paths.

Vertical incidence ionosondes located at Wallops Island and Fort Monmouth observed decreases of density at the peak of the F-region of approximately 30 per cent. The

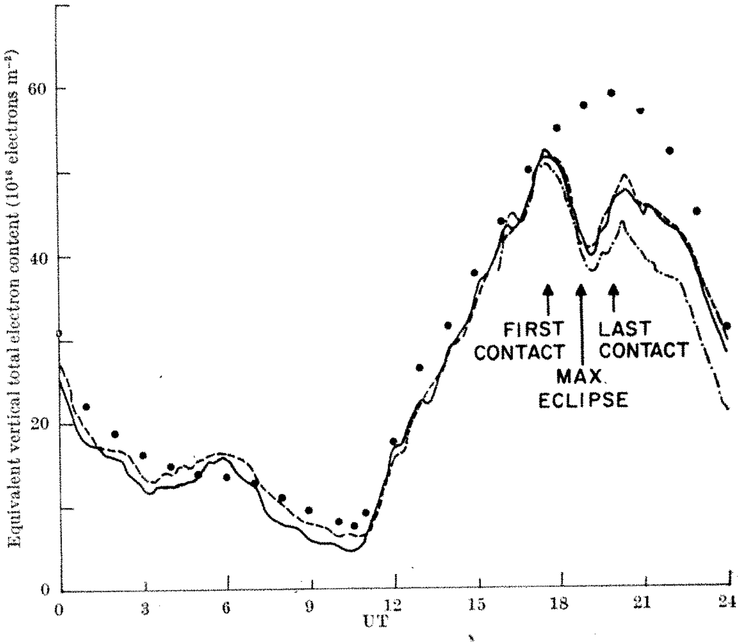

Fig. 2. Equivalent vertical total electron content on the eclipse day and on the three days preceding the eclipse. ———, ATS-3; . . . , smoothed mean of March 4, 5 and 6; - - -, ATS-5; —·—·—, Early Bird.

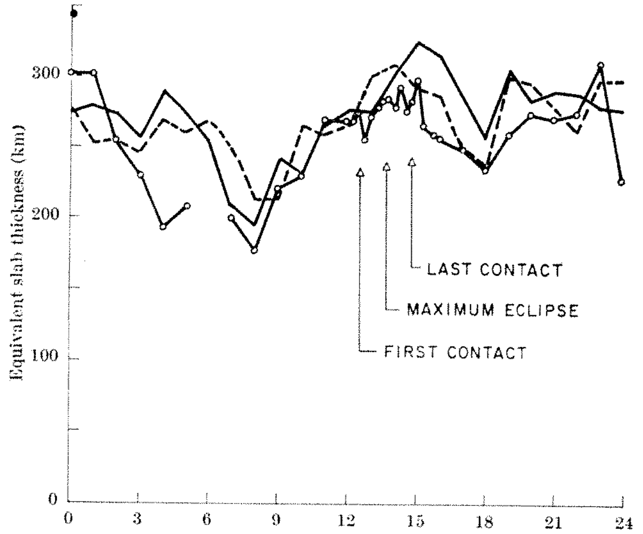

Fig. 3. Equivalent slab thickness of the F-region. ———, March 5; - - -, March 6; ○—○, March 7.

equivalent slab thickness of the F-region, shown in Fig. 3, was not significantly changed during the eclipse, at least not when compared with the two days preceding the eclipse. All slab thickness values shown in Fig. 3 were computed using TEC values from the ATS-3 path and ionosonde data from Wallops Island.

In spite of the fact that the solar eclipse occurred during a moderately disturbed period ($\sum_{24} K_{\mathrm{Fr}} = 33$) the eclipse effects were clearly predominant, in contrast to a report by King *et al.*[2], who observed that storm effects predominated during the June 10, 1964, eclipse near Woomera, Australia. The March 7, 1970, eclipse was also interesting in that TEC and $N_{\max}$ changed by approximately the same amount. This indicated that the expected piling up of electrons from higher heights to near the peak was more than compensated for by losses at the peak such that layer shape was maintained.

Synoptic Preview of Ionospheric Data taken at Fort Monmouth, New Jersey, during the Eclipse

Various ionospheric observations were made at Fort Monmouth during the eclipse of March 7. These included a readout from the topside sounder satellite Alouette 1, polarization and signal strength measurements from beacons in the S-66 and ATS-3 satellites, and bottomside ionograms from various locations. This letter is a preliminary view of how data from the ATS-3 observations are related to the vertical ionogram data obtained at Wallops Island kindly provided by R. S. Gray, ESSA Ionospheric Station, Wallops Island. We selected the Wallops Island ionograms for our comparison because the sub-ionospheric point (below 350 km altitude) for our path to ATS-3 is at 37·1° N, 75·5° W, rather close to the Wallops Island station at 37·9° N, 75·5° W.

The polarization measurements of the ATS-3 beacon (137·35 MHz) represent the expected picture for a solar eclipse close to local noon. Before first contact, the polarization angle (the total electron content) increased steadily. Then a turning point (or maximum) was reached when the data decreased to a minimum related to the maximum coverage of the eclipse. After the minimum the polarization increased until a second turning point (maximum) was observed. From then on the polarization descreased as it would during the afternoon of an undisturbed day. A similar variation was observed for the plasma frequencies, for example, F_0 and E_0, read from the ionograms.

At an altitude of about 300 km, first contact at the sub-ionospheric point was at 1225 EST. The first turning point in the ATS-3 observations, that is, the moment when the effects of decreasing ionization is noticed in the total electron content, was observed at 12(38 ± 3) EST, about 13 min after first contact. The ionograms from Wallops Island show the beginning of a decrease of the plasma frequencies in the F-region at 12(45 ± 4) EST. This time delay is more than can be explained by the more northern position of the ionosonde in comparison with the sub-ionospheric point—we estimate a delay of about 1–2 min due to the difference between locations. Thus we conclude that the effect of the eclipse is revealed in the total content along the path of the satellite about 4 min earlier than in the F-region observations. The E-region data from Wallops Island show the first reaction at 12(15 ± 2) EST, earlier than the time for first contact as seen from the ground at Wallops Island (1220 EST), and also earlier than the first contact time at 300 km altitude for the sub-ionospheric point (1225 EST). Although more detailed investigations are necessary, the early decrease of E_0 before the beginning of the decrease in total content seems to be compatible with the later reaction of the F-region.

Maximum coverage at the sub-ionospheric point (at 300 km) is estimated as 1343 EST. At this time the polarization data from ATS-3 indicated a reduction of only about 90 per cent of the total reduction observed. The minimum was reached at 14(06 ± 3) EST, 23 min after maximum coverage. The F-region minimum at Wallops Island was at 14(15 ± 8) EST. Again assuming a two min delay because of the distance between the two locations, there is a delay between the minimum in total content and the F_0 minimum of about 7 min. Again the E-region responds more quickly, reaching minimum at 1340 EST at Wallops Island (equivalent to 1338 EST at the sub-ionospheric point). This appears to be earlier than the time of maximum coverage at the E-region altitude.

The total content data resumed their normal decrease at 15(26 ± 3) EST. The F-region data reached normal values at 15(30 ± 8) EST and the E-region at 1500 EST. Last contact at the sub-ionospheric point was about 1458 EST. Again assuming the time difference of 2 min between locations, we find the E-region time coinciding with full illumination. F-region recovery is delayed by 30 min and recovery of total content by 28 min.

The data are consistent in so far as the comparison of F-region data with total electron content data is concerned, but the reaction of the E-region seems to be advanced in time relative to changes in illumination. This might have something to do with the distribution of zones of X-ray activity (Bomke *et al.* at the spring meeting of the US National Committee of URSI, 1970).

Observations of Ionospheric Electron Content during the March 7, 1970, Solar Eclipse

FARADAY rotation measurements of the VHF transmissions from the geostationary satellites ATS-I and ATS-III were carried out at several of our observatories in the United States during the eclipse. In addition, at Eastville, Virginia (37° 20′ 50″ N, 75° 54′ 13″ W), near Wallops Island, we measured the changes in the difference of the VHF and UHF phase path length between the ground and ATS-III. This satellite had been moved to a longitude of 85° W to permit a relatively good alignment of the geomagnetic field with the ray path from ATS-III to Eastville. This path crossed an eclipsed part of the F-region.

Fig. 1 shows the curve of the electron content versus time for Eastville on March 7, 1970. Corresponding curves obtained at Greenbelt, Maryland, and Rosman, North Carolina, show very similar behaviour. All these sites observed a volume of the F-region in which the eclipse was above 95 per cent. At Eastville the bulk of the ionosphere was totally eclipsed. In Fig. 1 a pronounced bite-out is seen which, using the previous day as a control day, can be estimated as about 20×10^{16} electrons m^{-2}. The relative bite-out was ~30 per cent. A 35 minute delay was observed between the time of minimum electron content and the time of totality.

The slab thickness, τ, defined as the ratio between electron content and electron concentration at the F2 peak, behaved in an interesting fashion. Some minutes prior to first contact it had a value of 430 km, which persisted up to 30 min before the maximum of totality when it fell rapidly, reaching a minimum value of 422 km at the middle of totality, probably due to the wiping out of the E layer. It then rose sharply to 480 km at the time the electron content reached its minimum value and decayed again to some 400 km after the fourth contact. In the time interval between totality and fourth contact τ took a sharp dip to 440 km, only to recover, reaching again 470 km.

Because the cooling of the upper ionosphere expected during the eclipse would reduce τ, the observed increase may be due to a marked erosion of the O^+ layer and consequent lowering of the $O^+ - H^+$ transition height.

The bite-out in electron content at stations away from the path of totality was surprisingly low, as indicated in Table 1.

Table 1. SIZE OF THE BITE-OUT IN ELECTRON CONTENT

	Eclipse magnitude (per cent)	Bite-out (per cent)
Eastville	≈100	≈33
Fort Collins	45	non-detectable
Clark Lake	28	non-detectable
Stanford	26	non-detectable

From the measurements at Eastville, both the columnar electron content I and its time derivative $\dot{I}$ were calculated. The latter is determined with great accuracy from the phase path length experiment.

As expected, near the end of totality—1836.30 UT—the rate of change of the columnar content reached its largest negative value of $(-7\cdot79 \pm 0\cdot13) \times 10^{13}$ electrons m^{-2} s^{-1}. This value can be introduced into the continuity equation to yield a value of the linear loss rate $\langle\beta\rangle$:

$$\langle\beta\rangle = \frac{-\dot{I} + \varphi + Q}{I}$$

where $\langle\beta\rangle$ is the weighted mean of the loss rate, φ is the excess inflow over outflow of plasma in the column of unit base between observer and satellite and Q is the total electron production rate in the column. Both φ and Q are unknown quantities and their upper limits must be estimated.

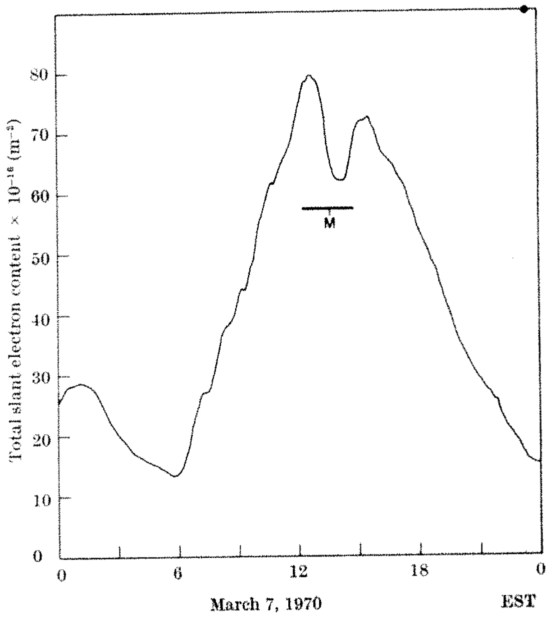

Fig. 1. Slant columnar electron content along the ATS-III to Eastville, Virginia, path. The values of electron content were determined by the method of Almeida *et al.*[3]. The horizontal bar indicates the duration of the eclipse.

The integrated production rate for an overhead Sun[1] was about 5×10^{14} electrons m^{-2} s^{-1} in 1966 when the solar 2,800 MHz radio flux was 100×10^{-22} W m^{-2} s^{-1} Hz^{-1}. If there is proportionality between radio flux and production rate, the overhead Sun production rate was about 8×10^{14} electrons m^{-2} s^{-1}, assuming a solar flux of 150×10^{-22} W m^{-2} s^{-1} Hz^{-1}. The actual production rate corrected for the solar zenith angle of 47° at Eastville at 1836 UT would be 5×10^{14} electrons m^{-2} s^{-1} if the eclipse had not occurred. At totality most of the light output from the Sun vanishes, but at X-ray wavelengths substantial radiation persists[2]. It is not known to what extent the EUV radiation responsible for most of the F-region ionization is obscured by the Moon, but if 99 per cent of the significant radiation is removed by the eclipse, then Q falls to a value of one order of magnitude lower than $\dot{I}$.

To assess the contribution of the Φ term, consider the plasma flux as divided into two components, one along the ray path and one normal to it. The parallel component has a vanishing integral along the column because the flux is certainly zero at the lower limit of integration near the observer and it is very nearly zero in the upper limit at the satellite not only in view of the small electron concentration (the spacecraft is beyond the plasmapause) but also because the geomagnetic field lines make a steep angle with the ray path to the satellite. Thus the only contribution to Φ is due to the normal component of flux which even using a very generous estimate is two orders of magnitude smaller than $\dot{I}$, so that the flux term has little influence in the determination of the value of the recombination coefficient.

The errors in $\langle\beta\rangle$ are therefore due to errors in measuring I and $\dot{I}$ and uncertainties in the estimation of Q during totality. If one disregards this latter influence, one obtains

$$\langle\beta\rangle \approx \frac{-\dot{I}}{I} = \frac{7\cdot79 \pm 0\cdot13}{(66\cdot8 \pm 2\cdot0)}\, 10^{-3} = (1\cdot16 \pm 0\cdot05)\, 10^{-4}\ s^{-1}$$

The determination of $\langle\beta\rangle$ from Faraday rotation measurements meets several difficulties not found with the phase path length technique. One obstacle is in the difficulty of measuring the time rate of change of the Faraday rotation angle Ω. This determination is quite "noisy" compared with the very high quality of the phase path change data. In addition, ground reflexions do not perturb the latter measurement but significantly alter the value of Ω and, because these reflexions are themselves affected by the polarization angle of the received wave, they have a marked influence on $\dot{\Omega}$.

An additional source of error comes from the fact that Ω changes not only in response to variations in electron content but also in response to alterations in the shape and the height of the layer. We have

$$I = \Omega / G$$

$$\langle \beta \rangle \approx \frac{-\dot{I}}{I} = -\frac{\dot{\Omega}}{\Omega} + \frac{\dot{G}}{G}$$

Because from the measurement of the Faraday rotation alone G and $\dot{G}$ cannot be estimated[3], the second term in the equation may introduce an appreciable error in ⟨β⟩. By combining phase path length and Faraday rotation measurements, both G and $\dot{G}$ can be estimated[3]. This was done at Eastville with the following result (at 1836.30 UT)

$$G = 5{\cdot}0 \times 10^{-17} \text{ rad m}^2$$

$$\dot{G} \cong -5{\cdot}5 \times 10^{-21} \text{ rad m}^2 \text{ s}^{-1}$$

Thus $$\frac{\dot{G}}{G} = -1{\cdot}1 \times 10^{-4} \text{ s}^{-1}$$

a value comparable with the value of ⟨β⟩. The use of Faraday rotation angle alone for the determination of the mean recombination coefficient may therefore lead to errors of the order of 100 per cent.

At present electron concentration profiles from the Wallops Island ionosonde are not yet available. When these data are available it is hoped that by investigating the behaviour of τ, G, and $h_{\max}$ during the eclipse, good information about the layer changes induced by the eclipse can be derived.

Variation of Electron Density in the D-region

This letter reports some tentative results of measurements of the D-region electron density made at the Pennsylvania State University during the solar eclipse of March 7, 1970, by the wave interaction technique described by Lee and Ferraro[1].

At Pennsylvania State University the eclipse was partial with about 90 per cent obscuration of the solar disk at maximum, which occurred at about 1838 UT. No data were obtained before 1809 UT because of a power failure and hence conditions before the eclipse are not known. The time required to obtain a profile was about seven minutes. This time could have been shortened to about two minutes, but as the interaction effect was expected to decrease during the eclipse the long integration time was adopted to improve the signal to noise ratio. In addition, rapid changes in electron density were not expected because the eclipse was only partial. An experiment to measure the electron energy loss coefficient, requiring about twenty minutes, was performed after every third electron density measurement; as a result, electron density measurements were not made continuously. The results of the energy loss coefficient experiment are described on page 1119.

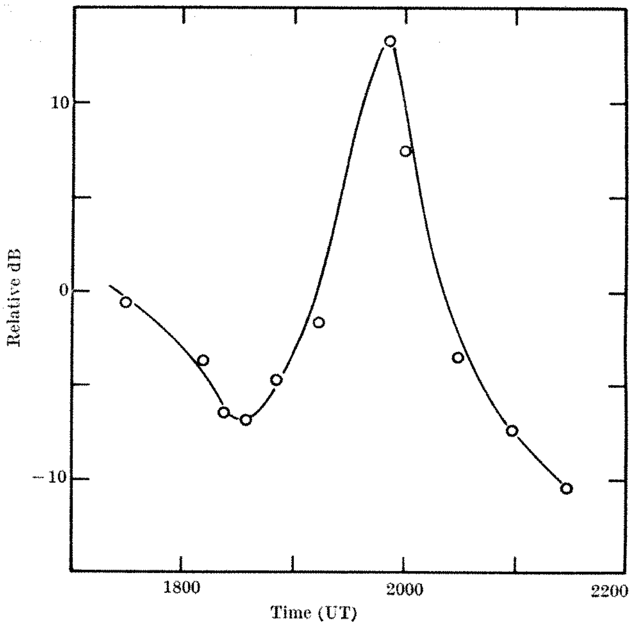

Fig. 1. Vertical incidence absorption measured at 2·2 MHz, March 7, 1970.

Fig. 1 shows the relative values of the measured vertical incidence absorption at 2·2 MHz. This information was obtained continuously and then averaged over intervals of seven minutes. The main eclipse effect at about 1830 UT and the effect of some other geomagnetic disturbance at about 2000 UT are clearly seen. Information on the effects of the X-ray flare which occurred at about 1610 UT was lost because of the power failure.

Fig. 2 shows electron density profiles for 1809, 1828, and 1913 UT on March 7, 1970, and for 1810 UT on March 11, 1970, for comparison with a normal day. These times

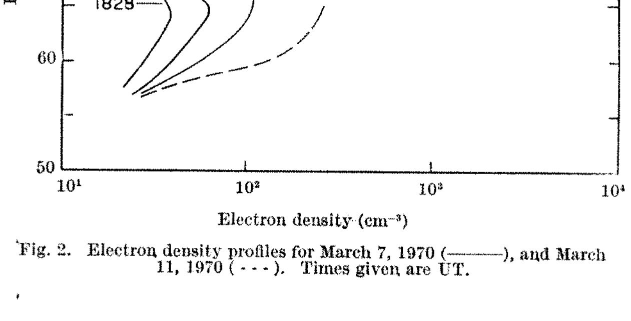

Fig. 2. Electron density profiles for March 7, 1970 (———), and March 11, 1970 (- - -). Times given are UT.

refer to the centre of the measurement interval of seven minutes. The chief eclipse effect seems to be above 70 km, with the electron density at lower heights remaining approximately constant until the event after the eclipse.

The interpretation of these results in terms of D-region chemistry is affected by at least two factors, the absence of pre-eclipse data at this location and the fact that the Sun was active during the period of the eclipse. The latter fact may be beneficial in that the covering and uncovering of active areas of the Sun may cause the 1–8 Å X-ray emission and the Lyman-α emission to vary differently during the eclipse and allow their effects to be sorted out. The absence of pre-eclipse and pre-flare data is a more serious problem as the response of the ionosphere to the eclipse will depend to some extent on how much it had recovered from the effect of the flare. Rowe *et al.*[2] have presented an analysis of the changes in electron density during a solar flare, which allows limits to be placed on the nitric oxide concentration. This analysis involves integration of the electron continuity equation starting at a point where the ionosphere is in equilibrium. In the present case such a starting point is not available; the analysis may have to be performed backwards, starting from a final point.

Steep-Incidence D-region Reflexions of Low Frequency Pulses during the March 7 Eclipse

THE path of totality of the eclipse of March 7, 1970, passed very near the Loran-C transmitter at Cape Fear, North Carolina. Loran-C transmissions are pulses with a carrier frequency of 100 kHz, a nominal bandwidth of 20 kHz, a nominal peak radiated power of 400 kW and are vertically polarized. The complete pulses of the ground-wave and the once reflected sky-wave signals were recorded by synchronized averaging techniques at a site 48·87 km west of the transmitter (azimuth 258·3°). The signals from a loop antenna in the plane of incidence (normal loop), a loop antenna perpendicular to the plane of incidence (abnormal loop), and a short whip antenna were recorded on separate channels at the receiving site. The data were later spectrum analysed, and the normal loop and abnormal loop measurements were used to derive the normally reflected and abnormally reflected sky-wave amplitudes at several frequencies in the Loran-C frequency band. The sky-wave amplitudes are normalized to the ground-wave signal as measured at the receiving site using the normal loop. Ionspheric reflexion coefficients can be deduced from these data after allowance for antenna radiation patterns and reciprocal distance effects.

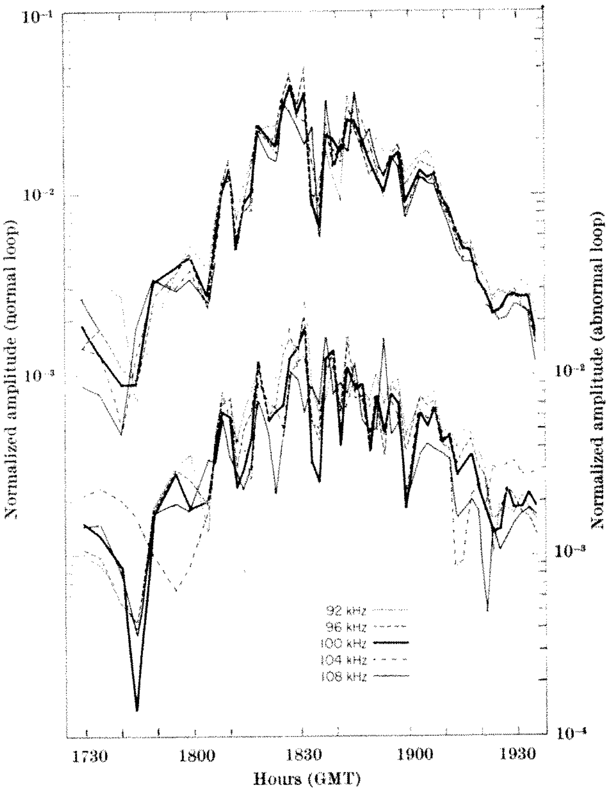

Fig. 1. Normalized sky-wave amplitudes for the normal loop (upper curves and left hand scale) and the abnormal loop (lower curves and right hand scale) as a function of time. Totality occurred at 1831 GMT.

Fig. 1 shows the magnitude of the normalized sky-wave amplitudes for five frequencies as a function of time during the eclipse. At D-region heights the first contact occurred at about 1711 GMT, the centre of totality at 1831 GMT, and the fourth contact at about 1948 GMT. Because of a certain amount of weak ground clutter in the signals, the sky-wave amplitudes both at the start and near the end of the eclipse, based as they are on weak ionospheric reflexions, are of doubtful significance. The measurements from about 1810 GMT to about 1920 GMT contain negligible spurious signals for two reasons: (1) the wanted signal-to-clutter ratio was large, and (2) the pulse delays were great enough during the main phase of the eclipse for the ground clutter to be separated out temporarily. It is these data that we would like to discuss. At the lowest and highest frequencies for which data are given, the transmitted signal amplitude is within the half amplitude points of the spectral distribution.

Both the normal loop antenna and the whip antenna respond to the normally reflected sky-wave signals. Because of differences in the antenna radiation pattern, the angle-of-arrival of the sky wave can be deduced. Fig. 2 shows the angle of arrival thus deduced (measured from the vertical) for the five frequencies used in Fig. 1. For our geometry, the angle of arrival is nearly equal to the angle of incidence on the ionosphere.

The most striking feature of these data is the oscillatory characteristics of the normalized sky-wave amplitudes. These characteristics also appear regularly during the sunrise and sunset transition periods on normal days. We believe the oscillatory feature results from interference between signals reflected from different levels in the D-region. The lower levels must, of course, be only partially reflecting. As the electron density distribution in the D-region changes during the eclipse, these reflecting levels can move with respect to each other, producing a pattern of alternating periods of constructive and destructive interference superimposed upon the general trends. In a smoothly varying ionosphere, levels of possible partial reflection are at heights $X = 1$, a region of strong coupling between ordinary and extraordinary waves, and at $X = (1 - Y^2)/(1 - Y_z^2)$, a level at which the equations describing the propagation have a singularity in the absence of collisions[1]. In a stratified ionosphere, likely contributors to partial reflexions are those levels in the D-region where a layer of enhanced (or diminished) ionization exists within what would otherwise be a monotonically increasing ionosphere. That such layers occur is indicated by the angle-of-incidence data. Periodically (for example, at 1814, 1823, 1835, and so on), the high frequencies show angles of arrival considerably smaller than the low frequencies. This can be interpreted in terms of a two-layer D-region; the low frequencies are reflected by a lower layer, while the high frequencies penetrate the lower layer and are reflected by the upper layer.

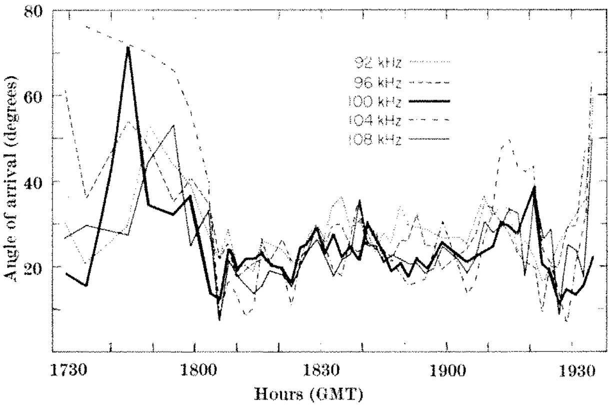

Fig. 2. Angle of arrival (measured from the vertical) as a function of time. The frequencies are the same as those used in Fig. 1. The data show that the various frequency components in the pulse appear to come from different parts of the sky.

The angle-of-arrival results (Fig. 2) are unexpected. They demonstrate that the different frequencies comprising the pulse appear to arrive from different parts of the sky. The most surprising aspect of the data is that at times the difference in angle of arrival of the various frequencies is as much as 20°, and that some of the angles of arrival correspond to surprisingly low "triangulation heights" of reflexion. Based on stationary phase concepts, a "triangulation height" of reflexion can be shown to be proportional to $\partial\psi/\partial I$, the rate of change of phase of the reflexion coefficient with angle of incidence[2]. Model profiles of electron density used in preliminary calculations for steep-incidence reflexion at these frequencies have yielded results showing that under certain circumstances $\partial\psi/\partial I$ can be very small indeed; hence the height of reflexion may appear to be lower than the height where the actual reflexion process occurs.

We have assumed that the D-region can be considered to be horizontally stratified. For a tilted, or rough region, the data would be very difficult to interpret. The response of the several frequencies in the Loran-C band that we have examined seem to be sufficiently uncorrelated that we have, in effect, a "broad-band" multifrequency sounding of the D-region. We believe that the data, despite their complexity, can be interpreted in terms of a horizontally stratified D-region and, within the framework of this model, it is our objective to derive from these data as much detailed information as possible about D-region structure.

Preliminary Results of a Radio Absorption Study at 3·5 MHz

The D-region of the ionosphere (50 to 90 km) is the main absorbing layer for radio waves. This is because in this relatively dense region the collision frequency is of the same order of magnitude or greater than the frequency of the absorbed waves. Electrons excited by a wave tend to scatter away the energy as heat rather than reradiate it as a wave. To a lesser extent the same is true of the E-region (90 to 150 km). Thus any phenomenon which depletes the D-region ionization, such as a solar eclipse, will decrease absorption. On the other hand, any phenomenon which increases the ionization, such as a solar flare, will produce an increase in absorption. These effects, therefore, can shed light on D-region processes. A continuous wave (A3) experiment at 3·57 MHz was conducted during the March 7 eclipse to study the influence of the eclipse on the absorption.

One interesting aspect is that the eclipse occurred at a time of intense solar activity. The days about the eclipse were, to varying degrees, magnetically disturbed, and several solar flares occurred on March 6, 7 and 8. The west limb flare on March 6 was responsible for a very intense magnetic storm and aurora on March 8.

King, Legg and Reed[1] have found that disturbed magnetic conditions can obscure completely at least some eclipse effects. The bottomside measures of f_0F2 displayed no eclipse effects during the disturbed eclipse of June 10, 1964, when the magnetic index, K_p, reached a maximum of 7. On March 7, 1970, however, magnetic conditions, though disturbed, were considerably quieter than this with K_p reaching only 4_+.

A 75 W transmitting station was set up at Waycross, Georgia, near the centre of the region of totality, and the receiving station was at Steinhatchee, Florida, some 190 km to the south-west and also along the path of totality. Each used half-wave dipoles, orientated parallel to the eclipse track to prevent any possibility of contamination of the desired sky-wave signal with ground waves. As the sky-wave for this base line and E or F layer reflexion heights must depart and arrive at angles of less than 45° to the vertical, the sky-wave is not attenuated appreciably by this configuration.

On the eclipse day, the signal level was sampled approximately every 10 min except for the period near totality when samples were every 1 to 2 min. Each sample was the mean of ten consecutive pulses, each 2 s

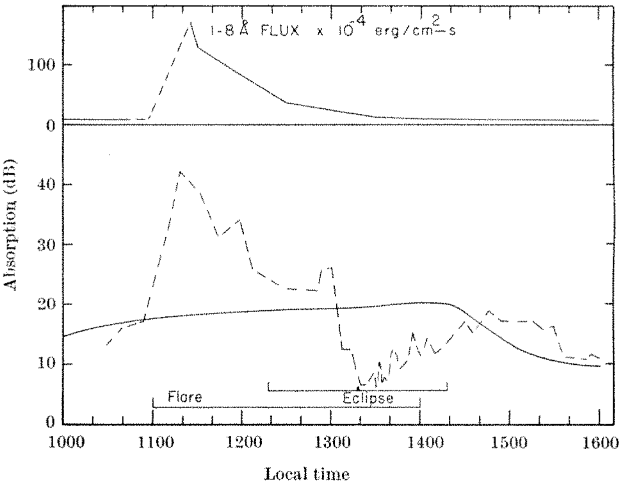

Fig. 1. Ionospheric absorption. In the lower plot, the broken line represents the observed absorption on the day of the eclipse, and the solid line represents the mean of the absorption on the control days. The upper plot is the 1–8 Å X-ray flux detected by the Solrad satellite. The broken lines represent a period at the beginning of the flare when the satellite was eclipsed by the Earth.

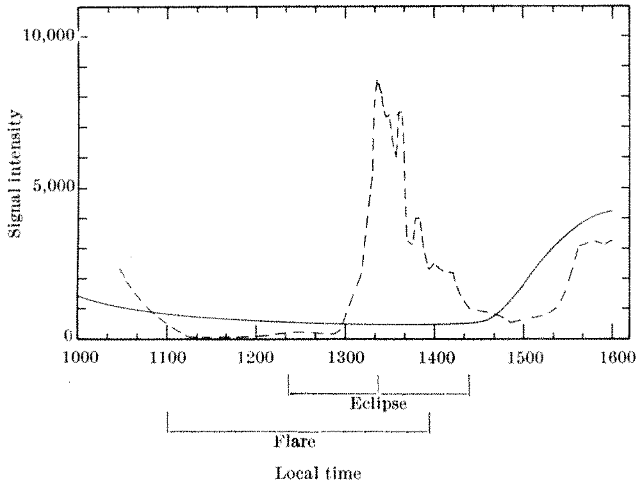

Fig. 2. Received signal intensity. The broken line represents the smoothed intensity of the received signal (the reverse of absorption) plotted on an arbitrary linear scale. The solid line represents the mean of the intensities on the control days.

long, emitted by the transmitter. On the control days, March 8, 14 and 15, the signal level was sampled at intervals of either 5 or 10 min.

Fig. 1 shows the relative absorption measured on March 7 as compared with the mean for the control days. For this preliminary report the zero level has been established arbitrarily at the theoretical value confirmed by Appleton and Piggott[2]. A solar flare of importance-2 occurred on the morning of the eclipse, about 2 h before the passage of totality. Consequently, Fig. 1 shows not only the anticipated decrease in absorption produced by the eclipse, but also a significant increase in absorption induced by flare radiation prior to the eclipse.

Fig. 1 also shows the evolution of the solar flare as seen in the 1–8 Å X-ray band from the Solrad satellite. There is a strong correlation between the X-ray flux and the observed absorption. The eclipse occurred near a sunspot maximum when X-rays in the 1–8 Å band are probably the chief source of D-layer ionization, although Lyman-α contributes to some degree[3].

After an approximate correction for the effect of the flare, we find that the maximum change in absorption produced by the eclipse is of the order of 14 to 15 dB. This is in good agreement with that obtained by the pulse sounding (A1) measurements at 3·86 MHz conducted by Bischoff and Taubenheim[4] during the annular eclipse of May 20, 1966. They also found an anomalous decrease in the absorption beginning some 28 min after the minimum absorption had been reached. Although somewhat obscured by the scatter in Fig. 1, in Fig. 2 (where the data have been smoothed and plotted on an intensity scale) a similar anomaly is seen to occur about 26 min after the absorption minimum.

From Fig. 2 it can be seen that the intensity of the received signal increased sharply between 1300 and 1320, remained relatively high for some 20 min, and then decreased sharply by a factor of 2·5 at 1340. With the anomalous rise in signal at 1346, the slope of the decay takes on a much more gradual appearance. Fig. 2 also shows that the centre of the sharply peaked region occurs at about 1328, some 8 min later than the time when the centre of the umbra passed the path midpoint at 80 km.

Finally, it seems that the decrease in absorption which consistently occurred on the control days by 1440 at the latest, as the transition to night-time conditions began, did not occur on March 7 until at least 1520. This 40 min delay seems to be real, but at present it is not certain whether it is the result of the flare, the eclipse or some other influence.

We thank Drs S. S. Prasad and T. D. Carr for suggesting the experiment and for valuable criticism, and Messrs Donald Roberts, Jerry Allnoch, Reavis Dixon and John Bridges for help.

Electron Energy Loss Factor in the D-region during the Eclipse of March 7, 1970

THIS letter describes the experimental observation of the electron energy loss factor (G) in the D-region during the eclipse. The experiment described is still in the development stage, but seasonal variations in G have been seen.

The G factor is important for the reduction of interaction experiments at the Ionosphere Research Laboratory, especially to describe experiments on the Luxembourg effect. The G factor enters the theory by way of the electron energy balance equation, which is used to obtain the excess electron energy (above ambient) that is imparted by a radio wave. This equation as given by Ratcliffe and Shaw[1] is

$$\frac{d}{dt}(\Delta Q) + G\nu\,(\Delta Q) = P(t)$$

where ΔQ is the excess electron energy, ν is the collision frequency, and $P(t)$ is the mean power supplied to an electron by the wave. G then represents the mean excess energy lost by an electron per collision.

The experiment is a variation of a disturbing-before-wanted (DBW) experiment used by Smith *et al.* (unpublished). Another form of interaction experiment is used at the Ionosphere Research Laboratory to determine the electron density profile (N) and the collision frequency profile (ν) (see, for example, ref. 2). In the DBW experiment the disturbing pulse is transmitted before the wanted pulse. The amplitude and phase interaction coefficients are then plotted as a function of the time spacing between the two pulses. Using a catalogue of disturbing-before-wanted simulation, G can be determined without the knowledge of the electron density collision frequency, with some range of error, because the DBW experiment is relatively sensitive to G. The use of both the extraordinary (X) and ordinary (O) mode disturbing wave gives a method of obtaining G with more reliability than is possible with either mode alone.

As mentioned earlier, seasonable variations in G have been seen showing a decrease in the winter. The average amplitude and phase interaction coefficients for June 1969 compared with those of January 1970 are shown in Fig. 1. The slopes of these curves are all that is meaningful for the determination of G; therefore the absolute levels are unimportant. The slope depends on N and ν somewhat, but simulations have shown their effect to be small compared to the effect of G. Physically, this is because at larger time delays the electron energy is lower with a larger G due to greater loss at each collision. The plots shown in Fig. 1 were compared to the DBW simulation catalogue. During June 1969, G was between $3{\cdot}5 \times 10^{-3}$ and 5×10^{-3}, and during January 1970, between $2{\cdot}0 \times 10^{-3}$ and $3{\cdot}5 \times 10^{-3}$.

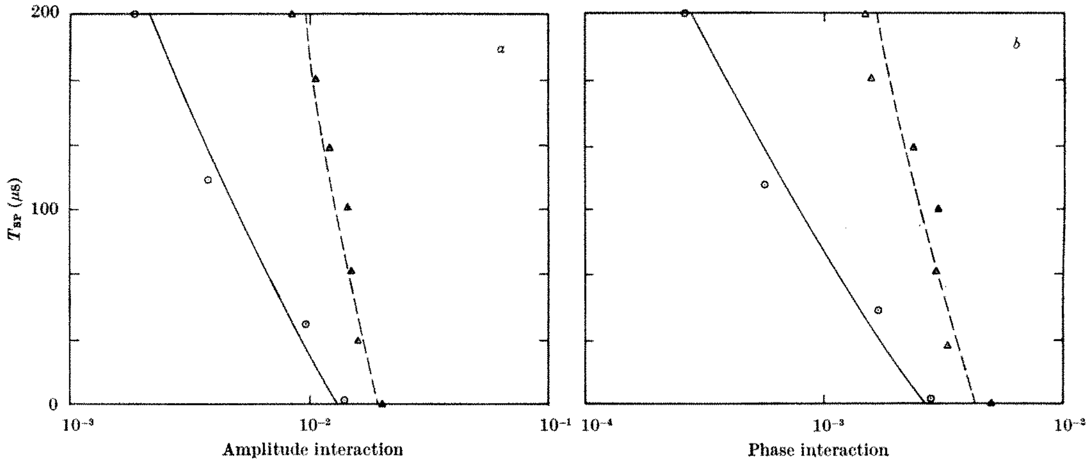

Fig. 1. Amplitude interaction (*a*) and phase interaction (*b*) for June 1969 (○—○) and January 1970 (△ - - - △), using X mode disturbing.

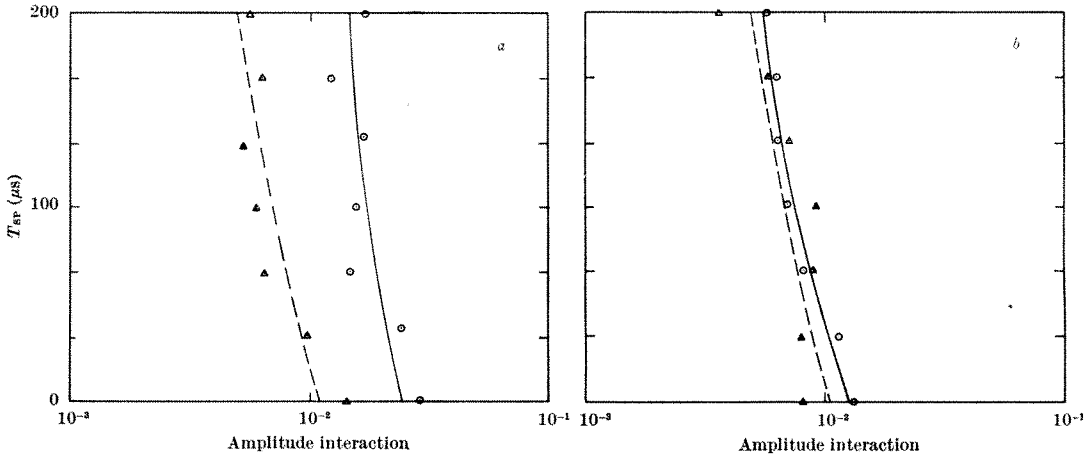

Fig. 2. Amplitude interaction for 1834 GMT, March 7, 1970 (△ - - - △), using (*a*) X mode disturbing and (*b*) O mode disturbing. ○—○, Reference.

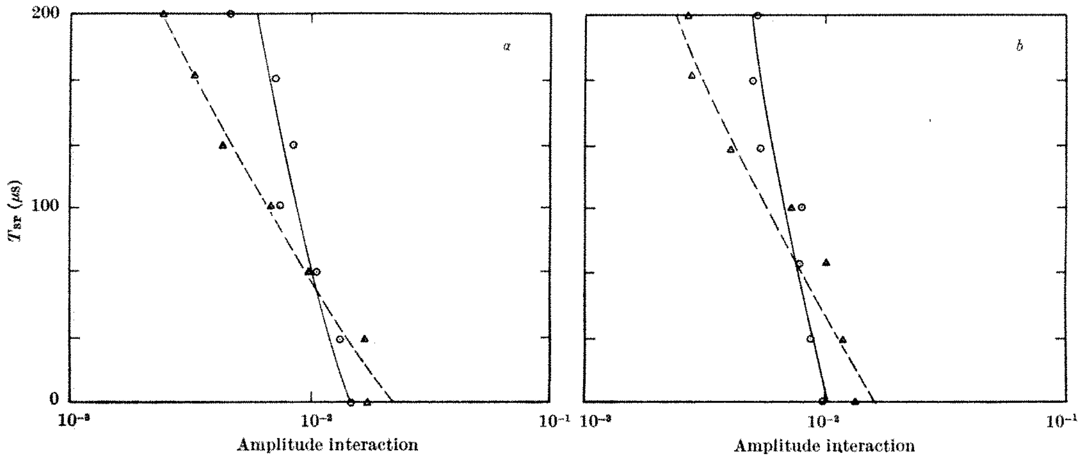

Fig. 3. Amplitude interaction for 1955 GMT, March 7, 1970 (△ - - - △), using (*a*) X mode disturbing and (*b*) O mode disturbing. ○—○, Reference.

Dalgarno and Moffett[3] calculated the theoretical temperature dependence of *G* in air to be approximately $T^{-3/2}$. Huxley[4], in a more detailed derivation, found this dependence to be $T^{-5/2}$ for air.

The experiment was run during the eclipse to search for a possible drop in the D-region temperature, which would show up as a rise in *G*.

The results will be shown in the form of a comparison of interaction coefficients for March 7 and an average of interaction coefficients for several days before and after the eclipse. This is done for different times during the eclipse, and each run was compared to those taken at about the same time on the reference. The reference used is an average of DBW interaction coefficients for February 25 and 26 and for March 10 and 11, 1970. Unfortunately, due to a power failure, no data just prior to the eclipse are available. It is also unfortunate that the phase interactions for March 7 are too noisy to use.

In Fig. 2*a* and *b* the curves for March 7 at 1834 GMT are compared with the reference, for the X and O mode disturbing respectively. The slopes compare well, so we conclude that there was no noticeable *G* change at 1834

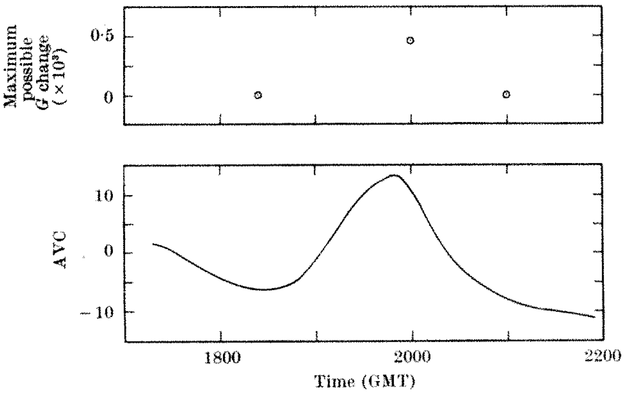

Fig. 4. Comparison of possible G change and receiver AVC.

GMT due to the eclipse. Fig. 3 shows the same curves for 1955 GMT. The March 7 data show a smaller slope than the reference implying a rise in G. Because there were no phase data, the change in G that this slope change represents is more uncertain. This change in G is estimated to be about $0\cdot2\times10^{-3}$ to $0\cdot5\times10^{-3}$ taking into account preliminary N studies made at the laboratory for the same times. Another run was made at 2100 GMT which shows results very similar to that for 1834 GMT. The slope change that appears at 1955 GMT may also be due to a relatively large N change and no change in G. This effect can be seen by comparing the postulated G change with the receiver AVC (average signal strength) (see Fig. 4). The increased absorption at 2000 GMT would cause some slope change in the interaction coefficients; hence G will not be as high as the first estimate that was made assuming no large N change.

The conclusion is that if there is a G change it is probably no more than $0\cdot3\times10^{-3}$. This would imply, using the $T^{-5/2}$ temperature dependence, a D-region temperature drop of about 10 K.

Response of the F-region Ionosphere to a Solar Eclipse

MEASUREMENTS of Faraday rotation of a linearly polarized signal have been used widely as a means of obtaining the integrated electron density or electron content in the ionosphere. Early measurements used the Moon as a reflector of radar signals and hence provided data only when the Moon was above the horizon. Faraday rotation measurements have also been carried out during a solar eclipse[1-3]. We report here some preliminary results of the Faraday rotation technique during the March 7, 1970, solar eclipse, using signals transmitted by the geostationary satellite ATS-3 at 137 MHz. Continuous observations were made at Norfolk, Virginia (36·56° N, 72·24° W), Turkey Point, Florida (29·95° N, 84·50° W), and Urbana, Illinois (40·069° N, 88·225° W). During the eclipse the satellite was located at 85·5° W. There are differences in the results from these three stations, but only the Norfolk data are presented here. The location of the 350 km subionospheric point at Norfolk is 33·87° N, 77·07° W.

The Faraday rotation measurement by a polarimeter gives only the relative change in polarization. We assume the orientation of the E-plane transmitted by ATS-3 to be 20° with respect to the spin axis, as measured by Klobuchar (unpublished). Our past experience agrees with this value. The daytime content is not very sensitive to the exact value of the transmitted polarization, however.

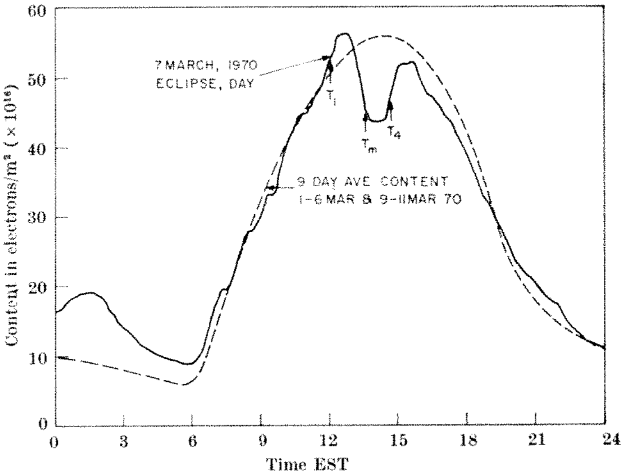

Fig. 1. Eclipse day and control day variation of electron content at Norfolk, Virginia.

Fig. 1 shows the average diurnal variation as well as the eclipse day variation in electron content. The average curve is the mean for the period March 1–11, 1970, excepting the values for March 7 and March 8 (March 8 was very disturbed). The first contact T_1 of the eclipse was at 1206 EST, and the content continued to increase for approximately 40 minutes after T_1 before it started to decrease when the Sun was approximately 40 per cent eclipsed. The minimum in content was fairly broad and was reached 39 minutes after totality, denoted by T_m. The content returned to its normal value about 43 minutes after fourth contact T_4. The change in content from the first maximum to minimum was $12\cdot8\times10^{16}$ electrons m^{-2}, or a decrease of 22·5 per cent. The change in content from the minimum to the second maximum was $8\cdot5\times10^{16}$ electrons m^{-2} or an increase of 19·5 per cent. These percentage changes are in agreement with those measured by Evans[4] for a 95 per cent eclipse in 1963, although the absolute values are quite different because of a difference in solar activities. The magnitude of the change reported here is four to five times larger than those observed by Evans for solar minimum conditions.

To simulate the eclipse behaviour of the F2-region, we have solved numerically the ionization equation of continuity and the neutral equation of motion. Detailed discussion of these equations, the neutral atmosphere model and ionospheric processes under normal conditions can be found elsewhere[5]. Here we will discuss only the perturbation introduced during the eclipse, and the results of computations.

The proportion of the solar disk unobscured by the Moon during an eclipse is given by the eclipse function $E(t)$ which is approximately V-shaped and is nearly linear for each segment. For simplicity, we approximate $E(t)$ by two linear curves. The eclipse function is then completely defined by specifying the time of first contact T_1, the time of maximum obscurity T_m, the time of fourth

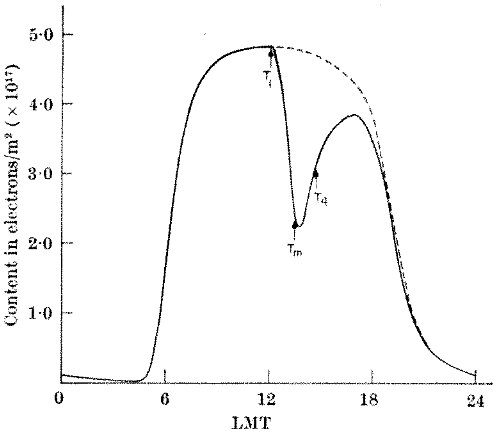

Fig. 2. Computed variation of electron content on an eclipse day.

contact T_4 and the percentage of maximum obscurity. Under the assumption that the Sun radiates uniformly across the solar disk, the intensity of the solar EUV radiation at the top of the atmosphere in the eclipse shadow region is given by $S'_\infty(t) = S \cdot E(t)$ where S_∞ is the intensity of solar EUV radiation under normal conditions. Because the production function of ionization is proportional to the intensity of the solar EUV radiation, the production function P' during the eclipse is given by $P'(t) = P \cdot E(t)$.

At present the precise variation of the exospheric temperature in the eclipse shadow region is not available although some rough experimental estimates have been made[4]. We have assumed arbitrarily that the decrease of the exospheric temperature is proportional to the eclipse function, and that the maximum exospheric temperature drop ΔT is 10 per cent of the minimum night-time temperature T_0 provided by Jacchia's model of the neutral atmosphere. The theoretical computations (ref. 6 and Shimazaki at the IAGA Scientific General Assemblies, 1969) have shown consistently a time delay between the time of maximum energy input and the time of maximum temperature of the atmosphere, so we also introduced a one hour time delay Δt between the time of maximum obscurity and the time of maximum temperature drop. The perturbed exospheric temperature in the eclipse shadow region is then given by $T'_\infty = T_\infty - \Delta T \cdot E(t - \Delta t)$. Here T_∞ is the exospheric temperature under normal conditions. The perturbed electron and ion temperature profiles in the shadow region are assumed to be

$$T'_e = (T_e - T'_n)\ \mathrm{Ch}(t)\ .\ E(t) + T'_n$$
$$T'_i = (T_i - T'_n)\ \mathrm{Ch}(t)\ .\ E(t) + T'_n$$

T_e, T_i are the temperature profiles for electrons and ions under normal conditions, T'_n is the perturbed neutral temperature profiles and $\mathrm{Ch}(t)$ is the normalized simple Chapman function. There is no time delay introduced for the temperatures of charged particles. A dynamo electric field given by Maeda and Kato[7] is also included in the computation. The dynamo field is assumed to be unaffected by the eclipse although there is evidence for a non-negligible effect[8].

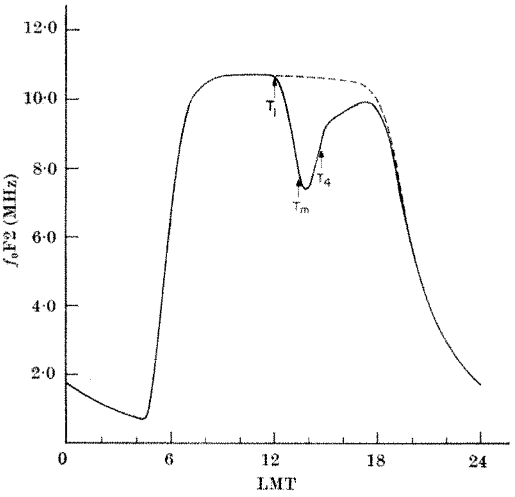

Fig. 3. Computed f_0F2 variation on an eclipse day.

Computations have been made for a station at 33·87° N, 77·07° W and a magnetic dip angle of 67°. The 10·7 cm solar radiation intensity used in the computation is 310×10^{-22} W m^{-2} Hz^{-1}. The computed variations of electron content, f_0F2 and neutral wind velocity vector at a height of 400 km are shown in Figs. 2–4 respectively.

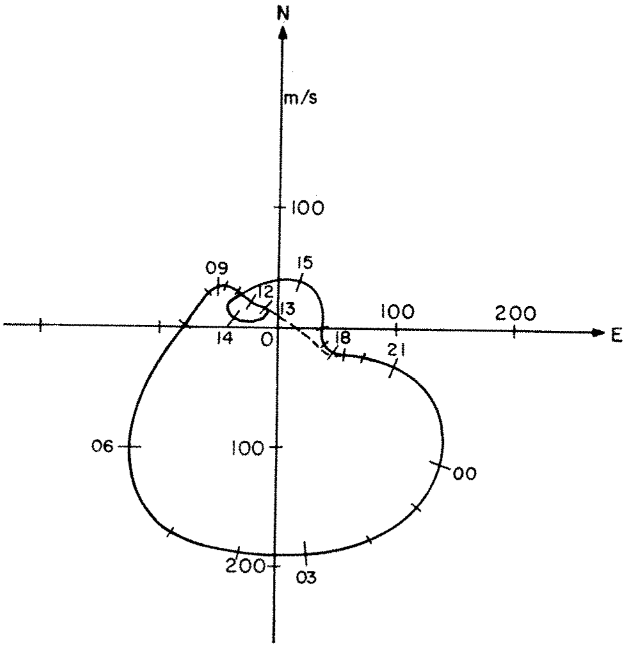

Fig. 4. Locus of wind velocity vector as a function of time at a height of 400 km on an eclipse day.

By comparing the computed variation of electron content with the data obtained at Norfolk we find that: (1) The general shapes of the computed and observed content curves in a normal day are somewhat different. The computed electron content increases rapidly during sunrise, reaches a plateau and stays relatively unchanged until sunset when the content begins to decrease very rapidly. But the observed content continues to increase with a constant rate after sunrise, reaches a maximum at about 1400 LMT, and then begins to decrease. (2) The computed electron content responds to the eclipse almost instantaneously and decreases much faster than the observed values. The observed content begins to decrease about 40 minutes after the beginning of the eclipse. (3) The predicted decrease in electron content during the eclipse is about $2 \cdot 3 \times 10^{17}$ m^{-2}, but only about $1 \cdot 3 \times 10^{17}$ m^{-2} in the observed data. (4) The time when the content reaches a minimum lags behind the time of maximum obscurity by about 25 minutes in the computations, while the observed time lag is about 45 minutes. (5) On the eclipse day the wind is quite different from the wind on a normal day.

The differences are difficult to reconcile. The eclipse effect on the electric field has not, of course, been taken into account. Other factors may have to be modified as more eclipse data become available.

Possible Detection of Atmospheric Gravity Waves generated by the Solar Eclipse

Chimonas and Hines recently suggested that the cool shadow of the Moon, moving at supersonic speed across the atmosphere of the Earth during a solar eclipse, should generate gravity waves which would build up into a bow wave[1]. They estimated a maximum pressure perturbation (at a distance of 10,000 km from the shadow) of 10^{-5} at ground level and 10^{-1} at 200 km altitude. The high altitude effect should leave an ionospheric signature in the form of a travelling ionospheric disturbance (TID).

Our group at Stanford has been studying the columnar electron content of the ionosphere for a number of years by measuring the Faraday rotation angle of the VHF transmissions from such geostationary satellites as ATS-I and ATS-III (ref. 2). These measurements have been made at a number of locations in North America. At the time of the solar eclipse of March 7, 1970, four stations were in operation in the western United States.

The gravity waves generated by the eclipse of March 7 should reach California some time after 1900 UT on that day according to the prediction of Chimonas and Hines. Fig. 1 shows the fluctuations in electron content observed along the Stanford to ATS-III and Stanford to ATS-I paths near that time. The 300 km ionospheric points of these paths are separated by about 600 km. The fluctuations were determined by subtracting a 31 min running mean from the observed electron content. The time periods preceding and following the interval depicted in the figure were characterized by very little fluctuation so that the undulations constitute a well isolated event occurring at about the time when the gravity wave was expected.

The two trains of oscillations, although strongly correlated, are not entirely similar, so that the association of peaks in one train with those in the other is a somewhat subjective matter. If the matching suggested by the letters in Fig. 1 is accepted, then, because ATS-III is east of ATS-I, the oscillations can be interpreted in terms of a disturbance travelling east to west. Electron content records from Fort Collins, Colorado (with the 300 km ionospheric point 1,280 km to the east of that on the Stanford ATS-I path), and Clark Lake, California (300 km ionospheric point 600 km south-east of that of Stanford), show disturbances similar to those in Fig. 1. The Clark Lake record is of poor quality, however. Estimates of the time shifts between similar features observed at any three of the four stations allow the horizontal phase velocity of the disturbance to be determined. The geometry is such that it is essential that the Clark Lake information be used, however, because the remaining sub-ionospheric points are nearly in a straight line.

A peak thought to be the same as that labelled *b* in Fig. 1 was observed at 1910 UT at Fort Collins and at 1928 UT at Clark Lake. Assuming that the bumps are matched correctly, the uncertainty in the time of the peaks at Stanford and Fort Collins is ±2 min, and the uncertainty is ±3 min at Clark Lake. Using these times and uncertainties, the horizontal phase velocity of bump *b* is 620 ± 120 m s^{-1} at a bearing of $279 \pm 25°$ east of north. (The direction given is that of the velocity vector.) Velocities computed for the other bumps are roughly the same. The maximum possible speed for *b* based on the Stanford ATS-I and Stanford ATS-III records is substantially lower, however.

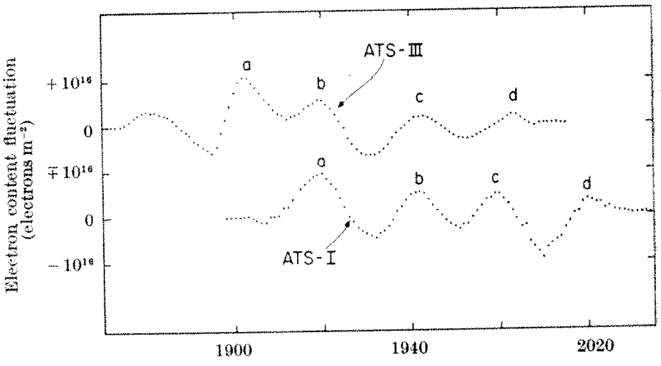

Fig. 1. Fluctuations in electron content along the Stanford to ATS-III and Stanford to ATS-I paths on March 7.

The amplitude of the undulation observed by the two Stanford stations is about $\pm 10^{16}$ electrons m^{-2}, and the background electron content amounted to some 60×10^{16} electrons m^{-2}. The relative amplitude of the undulation was therefore of the order of 1·5 per cent. The corresponding disturbance in the neutral atmosphere (if indeed the fluctuations observed were due to such a disturbance) may have been much larger because the direction of propagation, being roughly perpendicular to the geomagnetic field lines, may have resulted in a weak coupling between the atmospheric waves and the ionization. Disturbances travelling from east to west and having a similar character over the extent of the network (more than 1,000 km) have not been observed previously, although such disturbances travelling from north to south are often seen during geomagnetic storms[3]. The fact that these disturbances, of a rather unusual nature, occurred near the time predicted for arrival of atmospheric gravity waves due to the eclipse and that they came from the direction of the path of the eclipse implies a possible confirmation of Chimonas and Hines's suggestion.

Eclipse Observations at Arecibo, Puerto Rico, on March 7, 1970

THE data in this letter were gathered at Arecibo Observatory[1] using the incoherent backscatter technique[2]. Observations were made during the March 7, 1970, eclipse and on March 6 and March 8 as control days. The observations were made in two modes summarized in Table 1: one mode combining plasma line and single pulse autocorrelation data (unpublished work of Harper), the other using double pulse techniques[3] for improved altitude resolution in the bottomside ionosphere. The eclipse reached a maximum of about 30 per cent near 1430, with a semiduration of about 80 minutes.

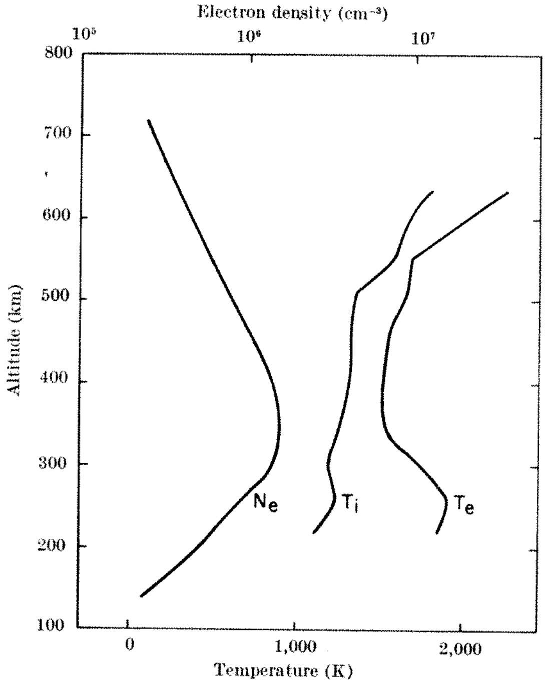

Fig. 1. Pre-eclipse electron density (N_e), ion temperature (T_i) and electron temperature (T_e) profiles for Arecibo Observatory, 1258 AST to 1313 AST, March 7, 1970.

Profiles of electron density N_e, electron temperature T_e and ion temperature T_i taken near the beginning, middle and end of the eclipse are shown in Figs 1, 2 and 3 respectively, as obtained in the plasma line mode. There are no striking effects in the temperatures. Apart from the post eclipse T_i at 500 km, the ion temperature profiles agree below 600 km within their 5 per cent error bars. The mid-eclipse T_e profile is systematically about 100 K lower than the other two profiles. But because density-temperature coupling has often led to T_e changes at Arecibo exceeding 1,000 K with negligible changes in the heat input, the question of eclipse effects on T_e must be viewed in terms of energy input. The plasma line intensities (yielding the derived parameter $KT_{\parallel}$) contain information regarding the photoelectron flux[4], but these intensities show no significant change during the eclipse.

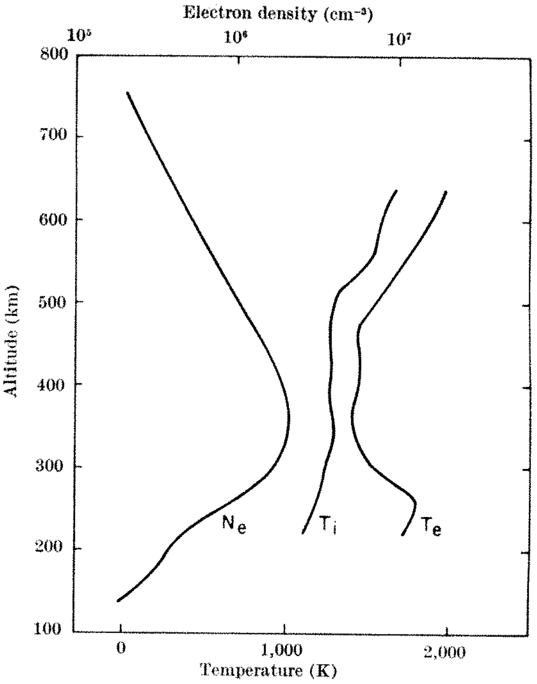

Fig. 2. Mid-eclipse electron density (N_e), ion temperature (T_i) and electron temperature (T_e) profiles for Arecibo Observatory, 1418 AST to 1433 AST, March 7, 1970.

Estimates of the electron-to-ion energy transfer rate

$$L_{ei} = 4{\cdot}8 \times 10^{-7}\ T_e^{-3/2}\ (T_e - T_i) N_e N_0^+ \ (\text{eV cm}^{-3}\ \text{s}^{-1})$$

give 10,000, 6,760 and 10,230 (±15 per cent) eV cm^{-3} s^{-1} for the pre-eclipse, mid-eclipse and post-eclipse periods respectively at 300 km; and 4,900, 3,340 and 6,600 (±15 per cent) eV cm^{-3} s^{-1} respectively at 260 km. This reflects a decreased heat input to the electrons in this bottomside altitude range of roughly 30 per cent during mid-eclipse, matching well to the percentage of totality experienced. These 15 per cent error bars allow the neglect of other terms, pending the full heat balance calculation including conduction and loss to molecular and atomic species. The heat conduction

$$Q_c = 7{\cdot}7 \times 10^5 \sin^2 I\ T_e^{5/2}\ \frac{dT_e}{dh}\ (\text{eV cm}^{-2}\ \text{s}^{-1})$$

downward through the 550 km level throughout the eclipse is consistent with $1{\cdot}8 \pm 0{\cdot}3 \times 10^9$ eV cm^{-2} s^{-1}. The heat conduction downward through 600 km was decreased at mid-eclipse by an amount that seems to be statistically significant, but could be explained simply by the increased topside electron density and the consequent electron-to-ion loss rate at this time.

The bottomside electron density profile decreased from the pre-eclipse to the post-eclipse period by an amount appropriate to the change in solar zenith angle; the bottomside mid-eclipse electron density is substantially

Table 1. SUMMARY OF THE ARECIBO OBSERVATIONS

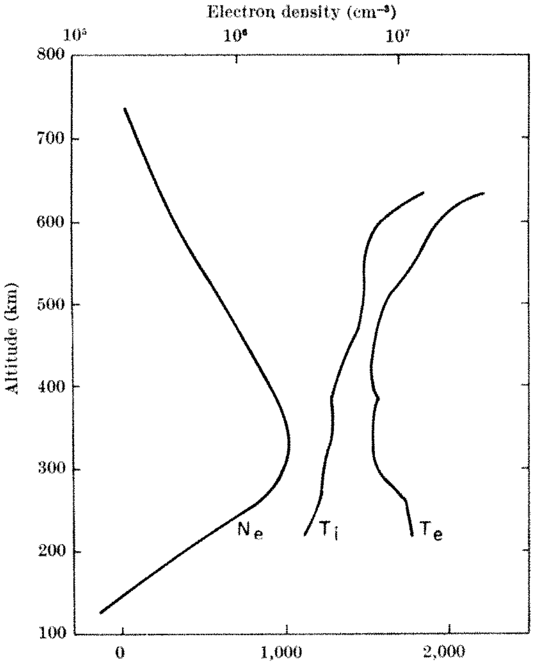

Fig. 3. Post-eclipse electron density (N_e), ion temperature (T_i) and electron temperature (T_e) profiles for Arecibo Observatory, 1525 AST to 1540 AST, March 7, 1970.

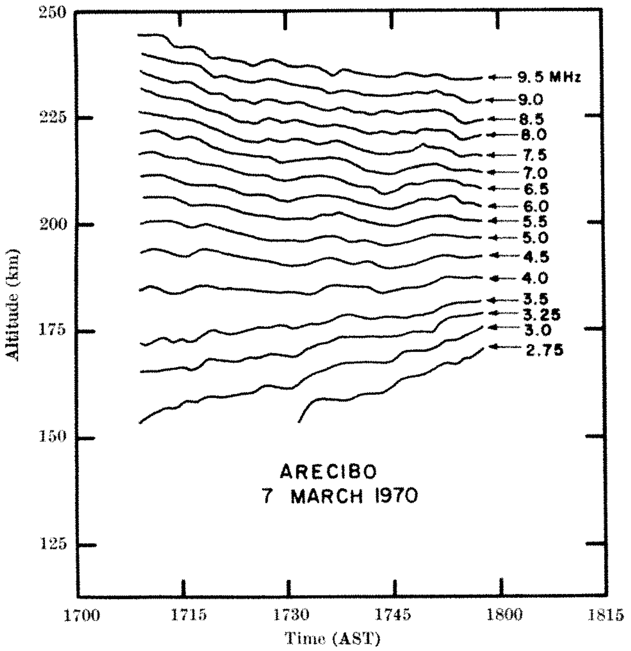

Fig. 4. Contours of constant backscatter power versus altitude and time. Transmitted pulse length = 300 μs; time smoothing ≈2 min. AST = GMT − 4 h.

lower near the E-region as recombination effects would lead one to expect. The ionosonde showed a distinct F_1 ledge (also visible in Fig. 2) for about 45 minutes centred on the eclipse, contrary to the normal situation at this time when there is usually only the mere suggestion of a ledge. The implications to ionospheric chemistry of this and of the mode 2 data are yet to be studied.

The topside electron density at mid-eclipse is seen to be substantially increased. It remains to be seen whether the mechanism for this increase is a decreased topside T_e and downward transport from well above 700 km, or an upward transport of the F-layer profile (vertical displacements of 40 km over time scales of the order of an hour are not uncommon, particularly on magnetically disturbed days).

It was suggested by Chimonas and Hines[5] that atmospheric gravity waves might be generated by a solar eclipse. Contour plots of constant backscatter power reveal a weak wave-like disturbance between 1725 AST and 1800 AST. Fig. 4 shows the contours for the time before and during the disturbance. (The subsequent section of data showed that the disturbance ceased about 1800 AST.) The values of the contours are normalized to the F-region critical frequency determined from an ionogram. The wave structure is apparent in the altitude region between the 3·5 and 8·0 MHz contours, that is, between 175 and 225 km, and the period is 15 minutes. At 215 km, the amplitude of the fluctuations in backscatter power is 6 per cent, which is four times the standard deviation of the measurement. If it is assumed that the disturbance originated from the point of closest approach of totality, then the velocity of propagation would be 200 m s⁻¹. The question of whether these waves are associated with the eclipse needs to be considered within the context of data from other stations.

It should be noted in passing that the data for March 8 are of little value as a control in view of the very high magnetic activity on that day.

This research was supported in part by a US Air Force Office of Scientific Research grant to Rice University. The Arecibo Observatory is operated by Cornell University under contract to the National Science Foundation and with partial support from the Advanced Research Projects Agency. We thank the staff of the Arecibo Observatory and Dean W. E. Gordon for their support.

Travelling Ionospheric Disturbances in Athens during the March 7 Solar Eclipse

Chimonas and Hines[1] point out that a solar eclipse, by interfering with the heat balance in the shaded portion of the atmosphere, can be expected to generate internal gravity waves, which should be detected at some considerable distance from the eclipse path.

Measurements in the Ionospheric Institute of the National Observatory of Athens several days before, after and on the eclipse day show some unusual variations of f_0F2 and of *h* min.F. Fig. 1 shows unusual increases in f_0F2 at 1900 and 2300 UT of March 8, and also an unexpected deep decrease at 0500 UT on March 9. The corresponding continuous record of *h* min.F for the same period indicates a strong variation between 0300 and 0600 of March 9.

Observations made by the National Meteorological Service of Greece indicated a variation of the order of 0·1 mbar between 2300 and 2400 UT on March 7.

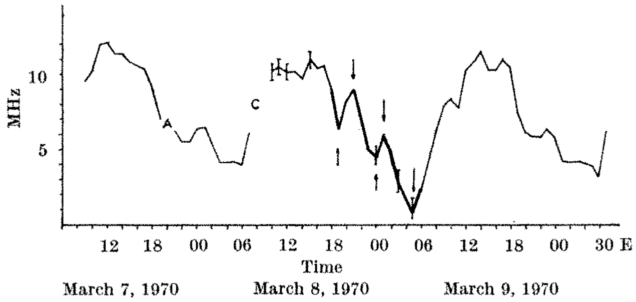

Fig. 1. Variation of f_0F2 in Athens during the period before, after and on the eclipse day.

Any attempt to associate these observations in Athens with the total eclipse over North America and Canada is premature. Only systematic observations from ionosondes and microbarographs around the world would justify the conclusion that the travelling disturbances were the result of an eclipse effect.

VLF Radio Signals observed in Newfoundland during the Solar Eclipse of March 7, 1970

THIS is a preliminary report on some naturally occurring radio signals observed in the very low frequency (VLF) band between 1 and 10 kHz during the solar eclipse of March 7, 1970. The observations were from a site close to the STADAN station near St Johns, Newfoundland, Canada, at geographic latitude 47° 44·9′ N, longitude 52° 43·4′ W, $L = 3{\cdot}46$. They formed part of a joint experiment in which VLF signals were also received in the magnetic conjugate area, at Halley Bay, Antarctica, and at a lower latitude, at Norwich, Vermont, USA.

The aim of the experiment was to record whistlers[1] during the eclipse period, and to search for effects which might indicate changes in the distribution of magnetospheric plasma along tubes of force of the geomagnetic field[2]. Unfortunately whistlers were not received in Newfoundland between 1800 and 2000 UT during the eclipse, although they were recorded during this interval on the control days and after 2030 UT on the eclipse day. Some interesting phenomena were found, however.

We used a single-turn, square loop antenna, of side 3 m, mounted with the plane of the antenna vertical and in the magnetic east–west direction. With this orientation the antenna did not respond to signals propagating along the magnetic north–south meridian. The path of the eclipse near Newfoundland was nearly parallel to the isoclinic lines, so that whistler-mode signals propagating along field lines with their "feet" in the eclipsed ionosphere were received preferentially. The signals were then amplified by a battery-powered, low-noise transistor amplifier, and signals from radio transmitters were removed by an *LC* low-pass filter tuned to 18 kHz. Twin-T band-reject filters at 16, 17·8, 100 and 112·6 kHz removed strong signals from GBR, NAA, Loran and a local navigation station respectively. Although the equipment was set up in a clearing in the forest some 2 km from the STADAN station, it was necessary to use two similar filters at 180 Hz to reduce interference associated with power-lines to an acceptable level. The amplified VLF waveform was recorded on magnetic tape. The intensity of the background signal at two frequencies, 2·90 and 5·36 kHz,

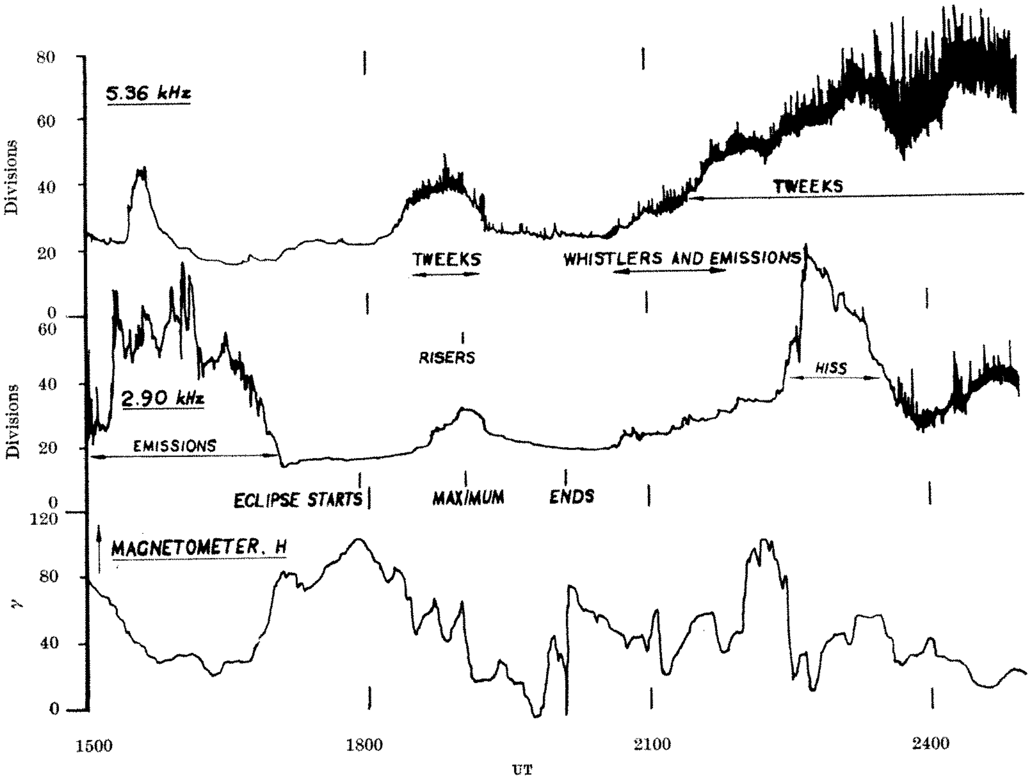

Fig. 1. Upper trace: the intensity of the background signal at 5·36 kHz, showing the occurrence of tweeks[4] during the eclipse and during the local night, each vertical trace corresponding to a particularly strong atmospheric. Middle trace: the intensity of the background signal at 2·90 kHz, showing the occurrence of chorus emissions before 1700 UT, of risers between 1901.31 and 1903.42 UT, and of hiss between 2230 and 2330 UT. Lower trace: the north–south horizontal component of the geomagnetic field, 1 γ being 1 nanoTesla. All quantities are increasing upwards.

was observed using a three-channel recorder, the paper chart moving at 2·5 cm h^{-1}.

A circuit, based on that of Ellis[3], minimized the effects of atmospherics[1]—energy radiated by lightning discharges. Fluctuations in the north–south horizontal component of the Earth's magnetic field were also recorded, using a flux-gate magnetometer.

Fig. 1 shows the chart recording for the 10 h period from 1500 UT on March 7, 1970. Geomagnetic activity during this interval was high, and from this record alone there is no definite evidence for a decrease in the magnetic field that could be attributed to a change in currents flowing in the dynamo layer of the ionosphere[4]. Before 1700 UT, VLF emissions of the chorus[1] type were recorded. These are particularly strong in the 2·9 kHz band, as they are at South Uist, Outer Hebrides, Scotland, at a similar magnetic latitude. There is also some energy at the higher frequency. After 2100 UT (1730 local time), the predominant signals were tweeks[1], which are atmospherics that have propagated for a considerable distance in the waveguide formed by the Earth and the night-time ionosphere.

Some 30 min after the eclipse starts (first contact was at 1755 UT) the intensity of the signals in both VLF channels increased. Tweeks were heard for nearly an hour, indicating that electrons in the lower ionosphere quickly recombined, the electron density falling to a post-sunset value. Night-time propagation conditions existed. After the maximum eclipse effect, the eclipse being total in the ionosphere above the receiving station, daytime conditions return for an hour and a half before sunset.

An unexpected phenomenon was observed at the time of totality in the ionosphere. A sequence of intense, rising-frequency, musical tones, known as risers[1], was recorded. Fig. 2 shows the frequency-time spectrogram of one such riser, received at 1902·41½ UT, rising from a frequency of 1·8 kHz to 2·4 kHz in $\sim$75 ms. The strong vertical lines are atmospherics which contain little energy below 4 kHz. The strong horizontal line at 10·2 kHz is due to an Omega transmitter. Some weak horizontal lines below 3 kHz, which are associated with harmonics of the fundamental frequency of the power-line signal, are also apparent.

Eighteen intense risers of this genetic type were recorded within 2¼ min, and their distribution in time is shown in Fig. 3. Three somewhat weaker, but otherwise similar, risers were received earlier, between 1827 and 1837 UT. One was received at 1845·37 and four more between 1847·53 and 1848·14 UT. With one exception, all these risers occurred at times when the strength of the magnetic field was rapidly decreasing.

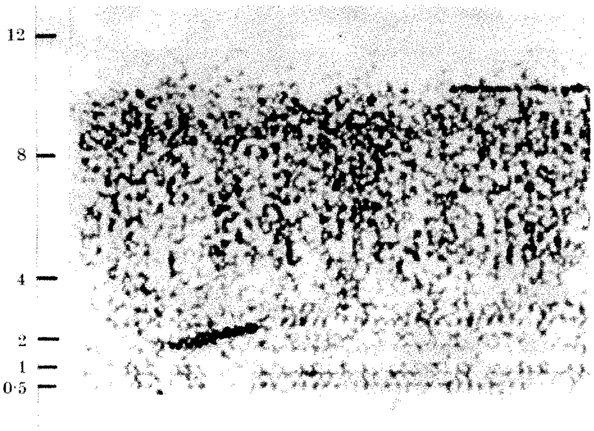

Fig. 2. Spectrogram of VLF waveform at 1902·41½ UT, showing a riser ($\sim$2 kHz), atmospherics, and an Omega transmission.

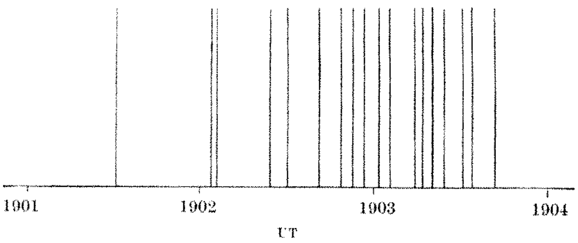

Fig. 3. Diagram showing times of occurrence of risers.

It is probable that these risers are produced by a transverse plasma instability in the magnetosphere (unpublished work of Burtis), in which a whistler-mode signal grows in intensity under conditions of enhanced magnetic activity and during the local afternoon. We suggest that they are received on the ground only at times close to eclipse totality because of the then much-reduced electron density—and hence absorption—of the D-region. An alternative explanation is that as the whistler-mode ray propagates through the ionosphere, its wavenormal is scattered downwards by the large horizontal gradients of electron density existing in the vicinity of the eclipse-induced "hole" in the ionosphere. The ray would then not be reflected as it would be by the undisturbed ionosphere. A contributory factor is the considerable attenuation suffered by waves of this frequency when propagating in the Earth–ionosphere waveguide[5], $\sim$30 dB/1,000 km at 2 kHz.

Strong whistlers were recorded between 2030 and 2200 UT. During this interval, some peculiar VLF emissions, with both rising and falling frequency-time characteristics, were received. For an hour from 2230 UT the dominant signal at 2·9 kHz had mainly the characteristics of hiss[1]. Analyses of these data, and of those obtained during the magnetic storm of March 8, 1970, are continuing.

We thank the many people who helped to make these experiments possible, and the Royal Society, NATO and the Science Research Council for financial assistance.

VLF Propagation Effects produced by the Eclipse

Very low frequency (VLF) transmissions from three locations (Omega, Haiku, 10·2 kHz; NLK, Seattle, Washington, 18·6 kHz; and NAA, Cutler, Maine, 17·8 kHz) were received at Umuarama Radio Observatory, Campos do Jordão, São Paulo, Brazil, during the total solar eclipse of March 7, 1970, by two receiving stations controlled by a rubidium oscillator. The phase outputs had widths of 0–100 μs (± 1 μs) and 0–10 μs (± 0·1 μs), and the recording time constants were 50 s in phase and in amplitude. The propagation paths were 12,900 km, 10,900 km and 7,900 km long respectively (see Fig. 1).

Fig. 2C shows the effect on the NAA–São Paulo path. The dashed curve shows the average phase change on a

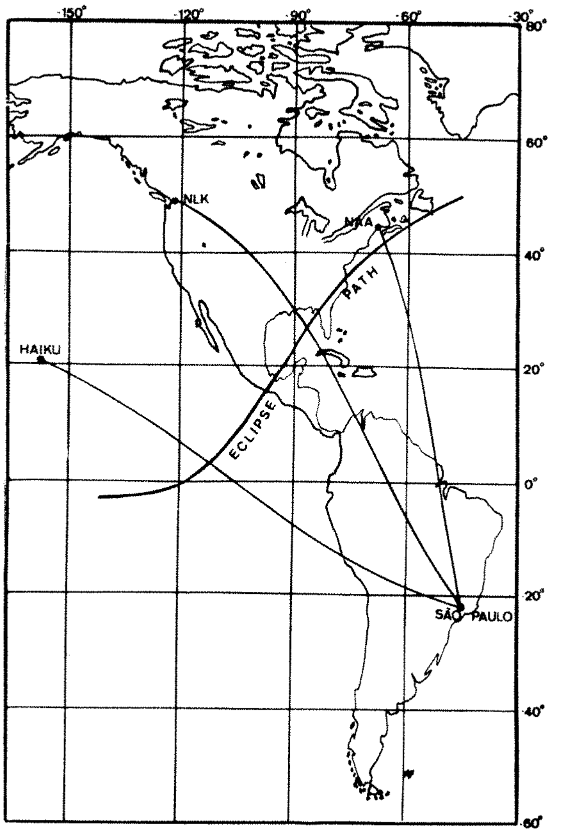

Fig. 1. The geometry of the propagation paths from Haiku, NLK and NAA to São Paulo and the path of totality of the eclipse.

normal day and the full curve the phase changes observed on the day of the eclipse. The times of first contact, maximum phase at ground level, and fourth contact are marked. The maximum phase delay was 4·5 μs which occurred nearly five minutes after totality crossed the path. The time interval between the onset of the phase retardation and first contact over the path was eleven minutes.

Two important points should be mentioned. (1) Because the VLF station at Campos do Jordão comprises only two receivers, the following tracking procedure was adopted (see Fig. 1). Stations Haiku (10·2 kHz) and NLK (18·6 kHz) were monitored until 1730 UT when the Haiku receiver was switched over to receive NAA. Monitoring of NLK continued uninterrupted. (2) A sudden ionospheric disturbance (SID) which occurred at 1605 UT affected the phase and amplitude of both Haiku and NLK, but of course was not recorded on the NAA–São Paulo path. We feel that the time difference of eleven minutes between first contact and the change in phase on NAA, which is much smaller than the 30–45 minutes reported in other observations (unpublished work of Hildebrand, and ref. 1), is a direct consequence of the SID.

The changes in amplitude, not shown in Fig. 2, were in general small, the maximum increase being less than 0·3 dB.

Fig. 2B shows the phase changes on the NLK–São Paulo path, and the effect of the SID can be seen clearly. First contact occurred at 1643 UT, during the recovery period of the SID. The time at which the phase change due to the eclipse began is marked as EEC, and was obtained by comparison of the phase and amplitude records. The amplitude had recovered to normal after the SID, and the commencement of the eclipse effect could be seen clearly. The maximum phase change was about 4·5 μs and the delay between phase maximum and totality over the path was about nine minutes. Amplitude changes were once again very small, the increase being nearly 2·4 dB.

Unlike the NLK and NAA paths which were fully sunlit throughout, the eclipse crossed the Haiku–São Paulo path during sunrise. The dashed line in Fig. 2A represents the normal average phase transition observed during sunrise, and the full line curve represents the phase changes on the eclipse day. The SID occurred 45 minutes after first contact. It is interesting that the effect due to the eclipse (EEC in Fig. 2A) had already begun before the SID occurred. It should be possible in principle therefore to determine the location of the active region on the Sun responsible for the X-ray emission resulting in the SID. It is difficult to specify when the maximum phase change due to the eclipse occurred because of the SID, but the maximum marked S occurred ten minutes before totality.

Hildebrand (unpublished) carried out VLF measurements in southern Brazil at frequencies between 9·37 kHz and 31·25 kHz during the total solar eclipse of November 12, 1966. One set of measurements was at steep incidence and another set was on an oblique path along the path of the eclipse. The observations at oblique incidence show a phase retardation of about 6·0 μs at 31·25 kHz, falling to 1·0 μs at 15·6 kHz and again rising to 4·0 μs at 9·37 kHz. The phase retardation of 4·5 μs observed at 17·8 and 18·6 kHz in our experiments is comparable with the 3·0 μs retardation observed by Hildebrand at 18·75 kHz. The maximum phase retardation of about 5·0 μs observed at 10·2 kHz on the Haiku—São Paulo path compares well with that of 4·0 μs obtained by Hildebrand at 9·3 kHz. Kaufmann and Schaal[1] have also reported observations on a frequency of 26·1 kHz during the eclipse of November 12, 1966. They found a maximum phase delay of 12·3 μs when the path of totality crossed the propagation path. Signals at 16·0 kHz from Rugby observed at Mount

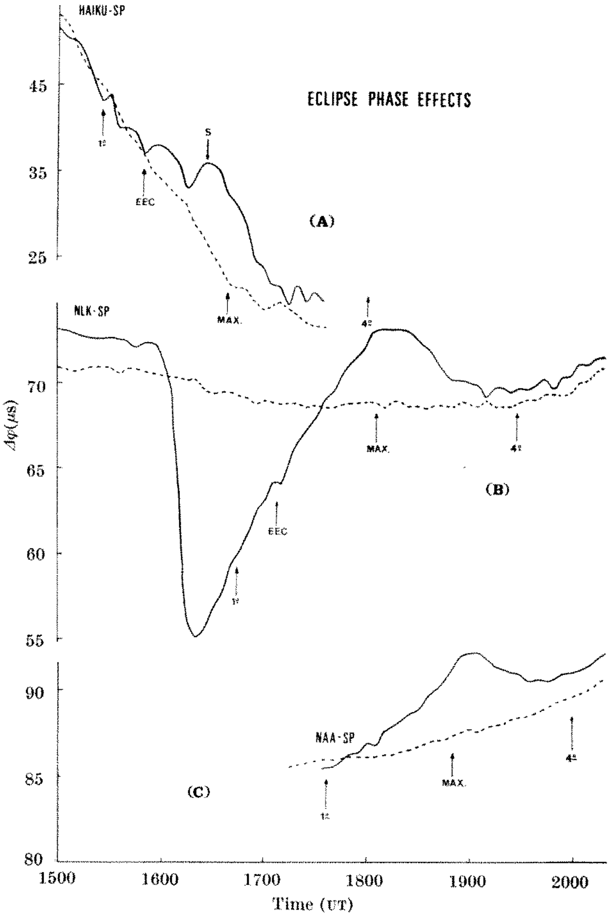

Fig. 2. Phase retardations for Haiku (A), NLK (B), and NAA (C) produced by the eclipse. The phase records for average normal days (dashed line) are also shown.

Stromlo, Australia, during the total solar eclipse of September 22, 1968, showed a phase delay of 3·0 μs (ref. 2). These observations seem to confirm Hildebrand's conclusion that there seems to be no distinguishable frequency dependence in the amount of phase advance.

The possibility of observing three VLF paths with two receiving stations was suggested by Dr F. H. Reder. This research was supported by the US Army Element Defense Research Office Latin America, Fundação de Amparo à Pesquisado Estado de São Paulo (FAPESP) and Conselho Nacional de Pesquisas (CNPq). Comparison of 100 kHz Pulse Propagation during Two Solar Eclipses

IN July 1963 the path of a solar eclipse swept across the Aleutian Islands of Alaska. Low frequency (100 kHz) pulse transmissions of the US Coast Guard Alaskan Loran-C chain were observed in the one-hop sky-wave propagation mode for paths near regions of totality. This letter compares the data obtained during this eclipse[1,2] with results from the March 7 event.

In the 1963 data the phase of the ionospheric signal was retarded nearly in proportion to the increasing solar obscuration, indicating a maximum apparent reflexion height near maximum obscuration. Following the maximum obscuration, the phase advanced with an overshoot following the end of the eclipse (see Fig. 1). This pattern is similar to a change in ozone densities at heights above approximately 65 km calculated theoretically. The amplitude of the LF pulse signal increased rapidly near eclipse totality, and reached a maximim value 4 min after the time of totality. These changes are similar to calculated changes in the density of atomic oxygen for heights below about 65 km, except for the 4 min delay which was attributed to ionic composition changes that would take longer than 4 min if $[0] < 10^8$ atoms cm^{-3} during the eclipse.

During the March 1970 solar eclipse LF pulse observations were made over several paths of totality or near totality along the east coast of the United States, again using the Coast Guard Loran-C facilities. The midpoints of the paths were from 34° to 56° N latitude, and the path lengths were from 1,000 to 3,000 km. The behaviour during this eclipse was quite different from those observed in July 1963 (see Fig. 1 in which the March 1970 data (Dana, Indiana to Bermuda path) are typical of all paths). Rather rapid phase retardations were observed in the signals near the eclipse totality, with the maximum apparent height of reflexion occurring 5 min after totality. The amplitude change was small with the maximum signal level occurring slightly before totality. It should be pointed out that on March 7, 1970, a solar flare occurred less than 1 h before the eclipse started. This flare appreciably affected all the LF sky-wave signals and recovery was not fully achieved by the time the solar eclipse began as shown in Fig. 1. The flare may partly account for the amplitude maximum occurring before the time of maximum obscuration, but a complete explanation of this phenomenon is not easy.

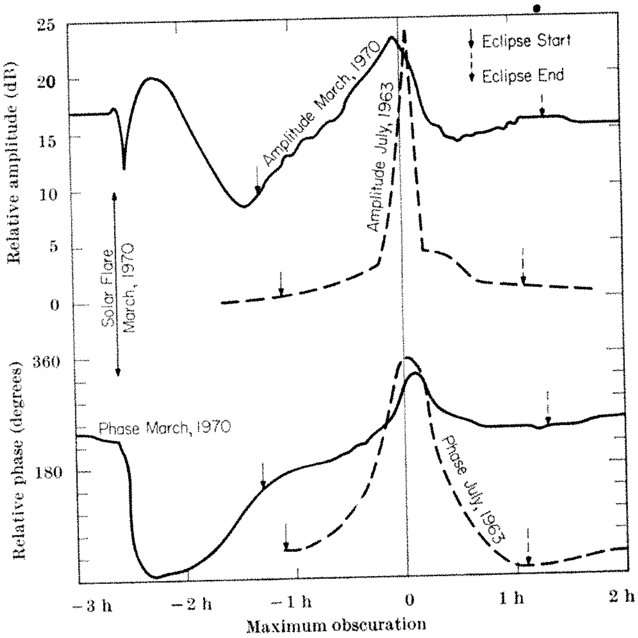

Fig. 1. Comparison of LF eclipse effects observed in July 1963 and in March 1970.

Aside from the problems produced by the solar flare preceding the eclipse, it is interesting to speculate on why the effects produced by the eclipse were so different in March 1970 and July 1963. The differences might have to do with the time in the solar cycle, different locations or path lengths for the measurements, or the season of the year. Both eclipses were near local noon, so the time of day should not be a factor. Routine LF sky-wave observations suggest that the propagation does not change appreciably with the solar cycle, apart from the effects of flares during solar maximum. The measurements in March 1970 covered several latitudes and several path lengths; if latitude or path length were a factor, the results from this eclipse should therefore have changed from path to path.

Seasonal changes in propagation do occur, however, and are similar in the United States and in the Aleutian Islands of Alaska. There is a lower reflexion height and greater ionospheric absorption in July than in March[3]. This could have to do with increased electron densities associated with increased production and concentrates of atomic oxygen during summer months, possibly by associative detachment of electrons from O_2^- by atomic oxygen. The daytime density profile of atomic oxygen would be expected to be lower in the summer than in March. Therefore the 5 min delay between the eclipse maximum and the phase peak observed in March could have been caused by the same mechanism that produced the delay of 4 min in the amplitude peak in the July measurements. If the apparent height of reflexion in March is determined by the density profile of atomic oxygen, few electrons would be produced by associative detachment by atomic oxygen at heights below this reflexion height because of rapidly decreasing atomic oxygen densities. Large amplitude changes, such as those observed in July, would not be expected to correlate with changes in the atomic oxygen density in this case.

Preliminary Comparison of Predicted and Observed Structure of the Solar Corona at the Eclipse of March 7, 1970

RECENTLY Schatten predicted[1] the structure of the corona at the eclipse of March 7, 1970. The prediction was based on a projection onto the celestial plane of the coronal magnetic field resulting from a Green's function solution for the magnetic potential between the photosphere and a spherical equipotential "source surface" located 2 radii ($R_{\odot}$) from the solar centre. Smith, in conjunction with L. Weinstein, photographed the corona using a 90-inch focal length Newtonian telescope at the NASA–Langley Research Center in Hampton, Virginia. A rapidly rotating sector wedge occulter with radially varying aperture (radial transmission filter) was designed specifically for this telescope and located just before the focal plane to reduce the steep average gradient of coronal brightness before the film (unpublished work of Smith, Henderson, and Torrey). The radial variation of transmission from unity at 4 $R_{\odot}$ to 0·0025 at the solar limb greatly facilitates photography of fine and intermediate scale brightness structure without overexposure by the average corona. This letter describes the chief points of agreement and disagreement in the preliminary comparison of observation with prediction.

Three defects in the photographs, two of which are evident in Fig. 1, must be explained before examining the coronal structure. At the left (east) edge is a diffuse circular image of the bright inner corona caused by reflexion off an uncoated glass window supporting the secondary flat of the Newtonian system. Interpretation of apparent structure beyond 1·8 $R_{\odot}$ in this region can be misleading. Second, a circular band near 2·2 $R_{\odot}$ is due to a slight non-uniformity in the radial transmission filter. Its location indicates that the filter was centred on the coronal image to within 2 arc minutes. Finally, non-uniform motion of the shutter created a series of faint linear dark bands across the shorter exposures which is not evident on this long exposure.

The structure of the middle and inner corona shown in Fig. 1 is typical of Lockyear's maximum type corona[2] although the maximum smoothed sunspot number occurred some sixteen months earlier. Our classification of a maximum corona is based upon several structural features. First, the usual dipole-like plumes of the rotational poles have been replaced by streamers, arches, and linear rays. Second, the height above the limb of most closed structures is usually very low. Third, there is a predominance of open, linear, ray-like structure much of which has a roughly radial orientation. It is interesting that the solar magnetograph observations of Howard (unpublished) indicate that by March 7 the magnetic polarity at the rotational poles had not yet reversed. Thus, on the basis of the 22-year magnetic cycle[3], the maximum might not have arrived by the time of the eclipse. The apparent discrepancy is not too surprising, however, bearing in mind the rather flat maximum of the present sunspot cycle.

The observation is compared to prediction by reference to Fig. 2 and Table 1. Figs. 1 and 2 have been enlarged to the same scale and the rotational axis indicated on Fig. 1 is uncertain by less than ±1°. The first two columns of Table 1 describe the coronal structures observed and list the heliographic position angle (measured

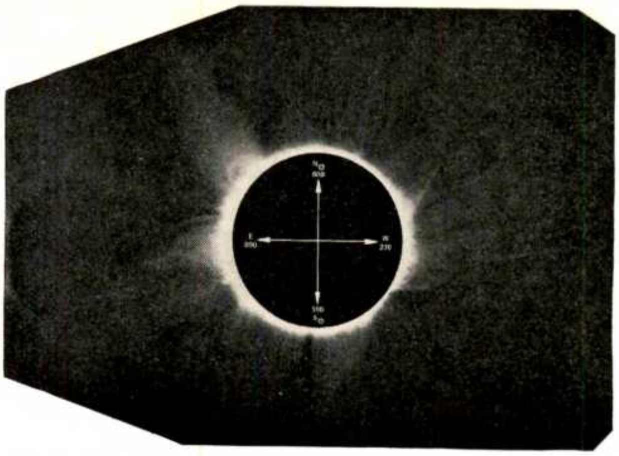

Fig. 1. The solar corona at 18 h 41 m 59 s UT on March 7, 1970. A radial transmission filter was employed to reduce the steep gradient of coronal brightness on this 2 s exposure. The Fluor-O-Dodge printer was also used to increase latitude in the reproduction process. A double reflexion exists at the east edge.

Table 1. COMPARISON AND PRELIMINARY EVALUATION

Observation		Prediction			
P.A.	Feature	P.A.	Feature	Comments	Preliminary evaluation
320–030	Many linear rays above low, elliptical arches	—	No prediction	North polar region: arch height 1/10 $R_{\odot}$ or less	—
031–069	Large helmet streamer (inverted "Y") over prominence at 052	030–070	Helmet streamers centred on 050	Maximum arch height of $\frac{1}{2}R_{\odot}$ agrees well with prediction	Clear agreement
069	Low, sharply cusped arches	075	Arch and ray	Arches are ~6° away	Qualified agreement
075	Short, narrow rays of a small condensation				
078–108	Non-radial active region streamers without helmet structure	100–120	Streamer without helmet structure	Partial overlap of features near limb, agreement improves with height	Qualified agreement
095	Small bright spot near the limb	095	Bright feature (condensation); small, tight arches	Condensations are + and − 20° away, although small arches could appear as a bright spot	Qualified disagreement
109–122	General region of condensation; central feature at 116	100–120	Streamers overlying arches at 100 and 110	An unusually high latitude condensation	Clear disagreement
123–148	Active region streamers and rays	120–150	Broad streamers without arches	Considered as a single feature for evaluation	Qualified agreement
—	—	145	Narrow streamer		
160–210	Broad streamer and helmet streamer (inverted "Y")	—	No prediction	South polar region: arch height $\frac{1}{4}R_{\odot}$ or less	—
210–236	Short, feather-like rays	210–230	Short rays	See Fig. 2	Clear agreement
		235	Narrow streamer		Qualified disagreement
236–268	Small helmet streamer (inverted "T") associated with prominence at 248	235–270	Broad streamer without arches	Prediction fails to include arches	Qualified disagreement
268–283	Faint, complex ray structure extending into mid-corona	278	Arch: rays in mid-corona	Except for the nested arches and prominence, unique identification of observed structure in this region is quite difficult. Arch height is near that predicted	Qualified agreement
288	Foot of a distinct arch and a small prominence	288	Bright feature (condensation)		Clear disagreement
292	Centre of symmetry of nested arches	292	Nested arches		Clear agreement
299	Long, narrow, radial ray; possibly a small condensation	—	—		—
283–297	Small helmet (inverted "Y") above nested arches; rays curve poleward	285–310	Helmet streamers centred on 302	Poleward curving features are considered as a single structure for evaluation	Qualified agreement
283–314	Poleward curving rays projected upon radial rays

Fig. 2. The structure of the solar corona predicted[1] for March 7, 1970.

counter-clockwise) of the intercept of those structures with the lunar limb. It should be pointed out that for a few non-radial, curvilinear structures of the middle corona this measurement procedure is somewhat artificial. The location at the limb of clearly identified features has been measured on contact positive copies with an r.m.s. error of 1·5°, which, when combined with the $\pm 2\frac{1}{2}°$ quantization interval of the calculation, leads to an uncertainty in the comparison of predicted and observed structures of ±3°. The descriptive terminology, inverted "Y" or "T", refers to the shape of helmet streamers as described in ref. 4. The next two columns of Table 1 give the position angle and description of the structure as described in ref. 1. The final two columns list pertinent comments and a preliminary evaluation of the prediction. "Clear agreement" means that the overall size, shape, and orientation of the structure predicted agree with that observed, in addition to the predicted location agreeing within the ±3° positional uncertainty of the comparison. "Qualified agreement" means that the prediction agrees approximately with observation, but that detailed agreement is lacking; or that the feature agrees well in structure, but the position disagrees by 3° to 6°. "Qualified disagreement" means that although the predicted structure may be nearby, it lies more than 6° away from the predicted position. "Clear disagreement" means a complete lack of positional and structural correlation.

In discussing this preliminary comparison, we first note that there are three cases of "clear agreement". It is particularly satisfying that the helmet at 052 degrees, the largest single structure visible at this eclipse, was correctly forecast. The maximum observed arch height agrees very closely with that predicted. The two cases of "clear disagreement" with the prediction are associated with the apparently erroneous location of coronal condensations which are usually considered to occur above active surface regions. It might appear that the location of the underlying active regions was not well known before the eclipse. That is not true, however, because such regions have a characteristic appearance on the magnetographic input data. Rather, something associated with the field calculations near active regions seems to be wrong. On the basis of experience with previous calculations and observations, we tentatively suggest that the source surface used in these calculations may have been located too high above the active regions. (We do not mean to imply, however, that by simple modification of the source surface one could incorporate the dynamic effects of solar flares into this fundamentally static calculation.)

Let us briefly examine this suggestion. First, use of a spherically symmetric source surface is clearly only an approximation because a spherically symmetric corona has never been observed. The structure seen at this eclipse is as good an example of this as any. Second, lowering the source surface above active regions will permit more magnetic field lines to leave the corona from lower heights than before and should reduce the size of the remaining closed structures. This is physically consistent with the generally higher temperature and density of active regions. Third, depressing the source surface should also reduce the somewhat excessive number of north–south oriented arches at present calculated near active regions because more of the adjacent, fringing field lines would then leave the inner corona rather than close downward. One observation at first seems to contradict this suggestion. The strength of the interplanetary magnetic field measured by spacecraft at 1 A.U. has not reflected the increased number of field lines to be expected from a reduced source surface height above the many active regions present at this maximum phase of the solar cycle. On the basis of Faraday rotation measurements of the field at 10 $R_{\odot}$, Schatten[5] has suggested that many of the field lines from active regions return to the Sun from the outer corona below the Alfven point near 30 $R_{\odot}$. Because such return does not influence the structure of the inner and middle corona, the spacecraft observations are not contradictory.

To summarize, the predominantly open structure of the predicted corona is in agreement on a large scale basis with the maximum type corona observed. The largest single structure apparent at the eclipse was correctly forecast. Detailed agreement of intermediate size features is best near older, more stable regions and is worst near coronal condensations. It is tentatively suggested that the technique might be improved by depressing the source surface above active regions, thus reducing the spherical symmetry of the model. This prediction may not be as good as that performed in 1968[6,7], but perhaps more has been learned concerning the influence of activity upon coronal structure.

We thank the Langley Skywatchers Astronomy Club and NASA–Langley Research Center for the use of their telescope. S. M. Smith thanks Milton Henderson and Leonard Weinstein for help at the eclipse site, and K. H. Schatten thanks John Wilcox and Robert Howard for help and interest in the calculation of coronal magnetic fields.

Prediction and Observation of the Coronal Structure for the Solar Eclipse of March 7, 1970

ON March 3, Schatten drew up a prediction for the coronal structure during the March 7 eclipse of the Sun[1], based on photospheric magnetic field measurements during the weeks just preceding the eclipse. I observed the eclipse under excellent weather conditions in Mexico, using cameras of 50, 120, 150 and 800 cm focal length. The pictures taken by the long focus camera show the fine structure of the inner corona, whereas the pictures with the shorter focus cameras reveal the streamer structure of the outer corona.

Table 1 compares the predicted and observed features. Position angles are measured counter-clockwise from the north pole.

Table 1. PREDICTED AND OBSERVED FEATURES IN THE CORONA OF MARCH 7, 1970

Prediction		Observation	
30°–70°	Helmet streamer, centred on 50°	30°–70°	Helmet streamer, centred on 45°; the most conspicuous feature of the corona
75°	Coronal arches		Missing
95°	Bright feature (condensation)	88°–116°	Bright region with coronal arches, superimposed on long streamer
100°	Coronal arches		
110°	Coronal arches		Missing
100°–120°	Streamer	100°–120°	Long streamer
120°–150°	Broad streamer without arches, inclined to the equator	126°–148°	Narrow streamer, inclined to the pole
145°	Narrow streamer		
235°	Narrow streamer		Missing
235°–270°	Broad streamer without arches		Missing
278°	Coronal arches		Missing
288°	Bright feature (condensation)		Bright region with arch-like structure
292°	Coronal arches		
285°–310°	Helmet streamer, centred on 302°	280°–315°	Broad (helmet ?) streamer

The most remarkable structure of the corona is the long helmet streamer in the NE-quadrant, which is connected with a large filament and is correctly predicted. The predictions for the intense and long double streamer in the SE-quadrant and for the helmet streamer around 300° are reasonably good. In the innermost corona the brightest regions are found over the activity zones, at 70°, 105°, 260° and 295°. The streamers in Schatten's drawing are radial or inclined to the equator, whereas the actual streamers have a preferential inclination toward the polar axis. The most serious discrepancy between prediction and observation is found in the SW-quadrant. Here the corona shows its lowest intensity—even lower than around the poles—and the predicted long streamer is completely absent. Coronal arches are predicted in all but the SW-quadrant. In fact, arch-like structures are found in all quadrants and the most pronounced of them just in the SW-quadrant at 250°.

According to Schatten the corona should be more elliptical in appearance than the corona of September 22, 1968. In fact, the ellipticity has diminished during recent years. At the representative distance of two solar radii from the centre the ellipticity amounted to 0·16 in 1966, to 0·06 in 1968 (ref. 2) and to 0·01 for the March 7 eclipse.

Solar UV Flash Spectrum 1400 Å–1960 Å

FIVE spectroheliographs were flown on an Aerobee 170 rocket from Wallops Island into the total solar eclipse to photograph and scan photoelectrically the ultraviolet and XUV flash spectrum of the Sun.

The five instruments were as follows: two Wadsworth mounting spectroheliographs with single gratings ($f=50$ cm, 2,400 lines mm^{-1}, linear dispersion 8·3 Å mm^{-1}), one with a wavelength range 150–435 Å (*a*), the other covering 700 to 1060 Å (*b*); (*c*) a modified Wadsworth mounting spectroheliograph designed to photograph the profile of the Lyman α line during the flash phase (Fig. 1); a plane grating (2,400 lines mm^{-1}, fifth order at 1216 Å) provided the high dispersion, followed by a Wadsworth mounted concave grating acting as the image forming element and "order sorter" ($f=50$ cm, 600 lines mm^{-1}, linear dispersion at Lyman-α 1·14 Å mm^{-1}); (*d*) a folded Wadsworth mounting spectroheliograph with single grating (Fig. 2, $f=50$ cm, 2,000 lines mm^{-1}, linear dispersion 9·75 Å mm^{-1}, wavelengths 1400–1960 Å); the folding mirror is introduced to reduce stray light before second contact in order to record the ultraviolet continuum in this wavelength interval; (*e*) a folded Wadsworth mounting spectroheliograph, with four scanning channels, covering 1300–2000 Å (Fig. 3), $f=110$ cm, 1,200 lines mm^{-1}).

There were three steps in the process by which the rocket was pointed at the Sun. First, coarse pointing was provided by an Aerojet Mark II tri-axial pointing system. Fine pointing, necessary because of the narrow field of view of the spectroheliographs, was accomplished by a solar eclipse sensor developed by NRL together with NASA Ames Research Center and Exotech Inc., Rockville, Maryland. An automatic gain control system provided a constant angular error signal independent of the rapidly changing intensity of the diminishing crescent, over the interval 1×10^{-2} solar constants to 2×10^{-4} solar constants. The telemetered value of the intensity between 6800 and 10700 Å was used to indicate the moment of second contact. After coarse acquisition of the Sun the sensor controlled the jet valves until the crescent was 5 arc s wide. Then the control of the valves was passed to rate integrating gyros (Honeywell GG87), which kept the payload pointing at the Sun within ±2·5 arc s, with a slewing rate of 2 arc s per second.

An electronic timer was started by the solar sensors when the width of the crescent was 5 arc s. Three different sequences were programmed for each camera which could be changed after lift-off by command from the ground in case of extreme deviations of the trajectory, which would have meant different scanning rates and different durations of totality.

The maximum apogee was 160 km, the deviation of the quadrant elevation from the calculated value was less than 0·6°, and the azimuth angle was within 6° of the predicted value. The roll angle of the rocket was decisive, because of the alignment of the crescent with the dispersion of the spectroheliographs, and was maintained within ±1° of the ideal value. The scanning speed of the Moon's limb over the edge of the Sun at second contact was about 0·42 arc s per second, and the duration of totality was 109 s.

The photographic instruments worked as planned, but the photoelectric instrument did not scan the spectrum

because of a malfunction of the motor which was supposed to drive the scanning mirror. Only limb darkening curves at discrete wavelengths could be obtained. Because of a failure in the recovery system, the payload sank into 1,770 m deep water in the Atlantic, 112 km from the Virginia coast. It was located and recovered on March 22 using CURV III (Cable-Controlled Undersea Research Vehicle) operated by the Naval Undersea Research and Development Center. Only the film strips of the middle ultraviolet instrument survived, because a cassette

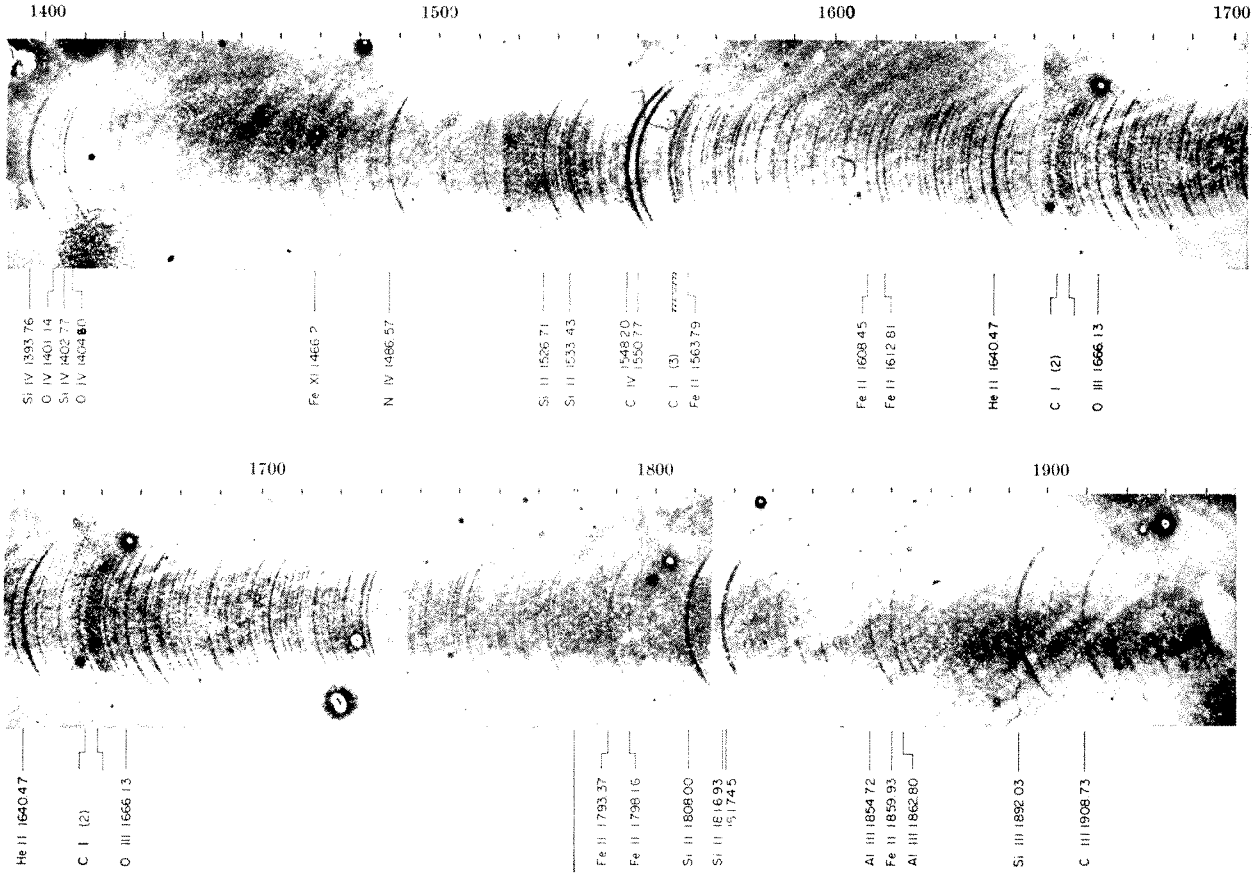

Fig. 4. Exposure No. 1. This is a five second exposure before second contact in which the Moon's limb occults the photosphere from −4·5 arc s to −2·2 arc s (the position of the Moon's edge relative to the solar limb, obtained from radar observations of the rocket trajectory).

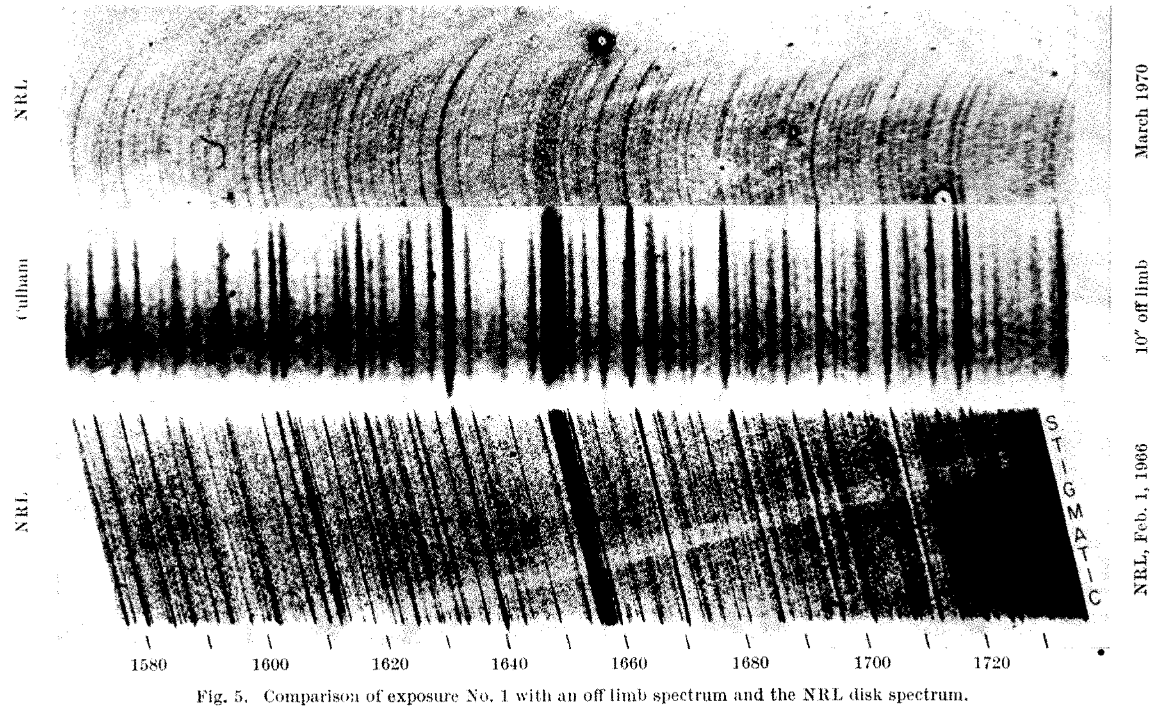

Fig. 5. Comparison of exposure No. 1 with an off limb spectrum and the NRL disk spectrum.

surrounding the film drum was coated with teflon, which slowed down the electrolysis in the salt water between the film and the aluminium of the cassette. The films were developed in straight Kodak D19 developer for 80 s at 2° C.

Fig. 4 shows spectrum No. 1, which represents the combined outer limb photospheric spectrum, the chromospheric spectrum and coronal spectrum. The photospheric continuum above 1800 Å is visible, but the background fogging makes any quantitative measurement impossible. The silicon continuum below 1525 Å can be seen.

Although a complete identification list cannot be given yet, some characteristic features of the identified lines can be discussed.

(*a*) Lines from neutral elements: (1) Many Si I lines between 1543 Å and 1565 Å have been identified by comparison with wavelength measurements in an arc spectrum by Radziemski and Andrew[1] (Table 1). All Si I lines show a crescent length which is slightly longer than the crescent of the photospheric continuum. Therefore they originate in the very low chromosphere. Fig. 6, which shows a sequence of spectra before and after second contact, verifies this. The Si I lines have all disappeared in the 1·6 s exposure obtained shortly after second contact, but they are still visible in the 1·6 s exposure shortly before second contact. All other lines remain. (2) In the wavelength range 1560 Å to 1660 Å the C I lines in Table 2 have been identified. The appearance of the C I lines is quite different from that of the Si I lines. Their crescent is longer, nearly equal to that of the Fe II lines. (This can be seen by comparison of the C I lines at 1561 Å and the nearby Fe II lines at 1558·71 Å and 1559·10 Å.) The time sequence spectra of Fig. 6 substantiate this. All Si I lines disappear shortly after second contact, but the C I lines are still there with only slightly changed intensity (see Fig. 6, spectra 3 and 6). The C I lines also show quite different behaviour to other lines in their disk to limb intensity change. This can be seen in Fig. 6 (where the solar disk spectrum was obtained by Purcell and Tousey[3]) comparing the Fe II lines at 1608·45 Å, 1610·93 Å and 1612·81 Å and the nearby C I lines at 1613·4 Å, 1613·9 Å and 1614·7 Å. The disk and the eclipse spectra show approximately the same density for the Fe II lines, while the CI lines are barely visible in the eclipse spectrum, but are clear in the disk spectrum. (The appearance of the 1658 Å C I multiplet in the disk and the limb spectrum confirms this.) Furthermore, the prominence shows very clearly in C I (and He II) but diffuse in more highly ionized lines. It is therefore very likely that the C I lines represent the spicules. The fact that the spicules shield each other when seen at the limb would explain this behaviour of the C I lines. (The amount of spicule surface seen at the limb is approximately the same as seen on the disk.)

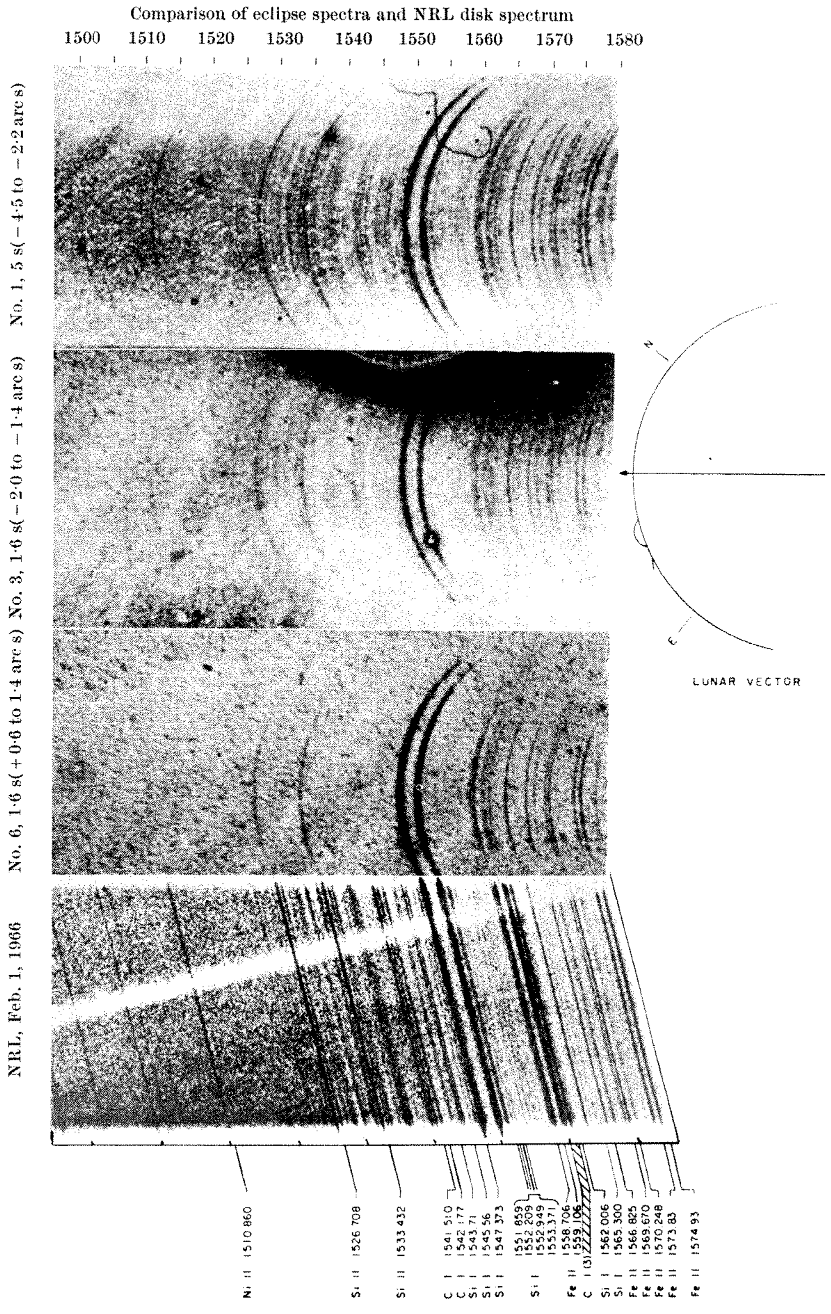

Fig. 6. A sequence of spectra before and after second contact. For exposure No. 1, see caption to Fig. 4. No. 3 was exposed to 1·6 s just before second contact when the coverage of the Sun by the lunar limb was −2 to −1·4 arc s. No. 6 is a 1·6 s exposure just after second contact when the coverage was +0·6 to +1·4 arc s.

Al II (1670·79 Å) is very similar to the He II line. This identification seems to be justified in view of the crescent length, which is much longer than that of the Fe II lines. Burton *et al.*[5] identified this line as Fe II, blended with Al II. (3) The Si II lines (1526·71 Å, 1533·43 Å, 1808·01 Å, 1816·93 Å and 1817·45 Å) also extend into the upper chromosphere. The strong, longer wavelength lines at 1808 Å, 1816 Å and 1817 Å can be seen further than 7 arc s. (4) The numerous Fe II lines are considerably weaker than the Si II lines. They disappear between 4·9 and 5·7 arc s into the chromosphere.

(*c*) Lines from two times ionized elements: (1) C III (1908·73 Å) (ref. 5), O III (1666·13 Å, $2p^2\ {}^3P_2$–$2p^3\ {}^5S_2$) (ref. 5), Al III (1854·72 Å), (1862·80 Å) and Si III (1892·03 Å) belong to the strongest of the spectrum, but their crescent length is smaller than that of the He II line. The limb-brightening of the O III line (1666·13 Å) is remarkable (see Fig. 5). The appearance of the prominence is very weak in all these lines.

(*d*) Lines from three times ionized elements: (1) These are C IV (1548·20 Å and 1550·77 Å), O IV (1401·14 Å and 1404·80 Å) (ref. 5) and Si IV (1393·76 Å and 1402·77 Å). The strongest lines in the available spectrum are from C IV. We estimate that these lines extend up to more than 17 arc s into the corona.

(*e*) Highly ionized elements (coronal lines): We can see three lines which are easily identified as coronal lines because of their crescent length, approximately 180° on spectrum 1. The lines are weak and diffuse. The quality of the spectrum in this region is poor. The wavelengths of these lines are 1425 Å ± 2 Å, 1448 Å ± 2 Å and 1467 Å ± 1 Å. Burton *et al.*[5] identified a line in the off limb spectrum at 1445·89 Å as the forbidden transition of Fe XI ($3p^4\ {}^3P_1$–$3p^4\ {}^1S_0$). The line at 1467 Å is the strongest of the three lines mentioned. All three lines are within the predicted wavelength range.

We thank our colleagues at NRL and are grateful for the help of many people and institutions, including Mr J. F. Meier and his group at Aerospace General, Fairchild Hiller Technical Services Operation, NASA Ames Research Center, Exotech Inc., NASA Goddard Space Flight Center, and NASA Wallops Station. The recovery was by the US Navy Supervisor of Salvage, the Naval Ship Systems Command, the Naval Undersea Research and Development Center in Pasadena, the USS Opportune and the Service Squadron Eight in Norfolk. We particularly thank Mr R. T. Long, NASA Wallops Station. This experiment was supported by NASA.

Rocket Observations of the Corona on March 7, 1970

On several occasions we have made non-eclipse photographs of the outer corona between 3 and 9 solar radii, using a rocket-borne coronagraph[1]. The instrument consists of two small Lyot coronagraphs placed side by side. Solar occultation for each is by a circular disk placed 76 cm in front of the 25 mm objective aperture. The disks for the two instruments are mounted on a common spar, on posts which have different spatial orientations, so that the coronal sector obscured by one post is not obscured by the other. Kodak I–D emulsion is used to give maximum photographic speed for coronal light with an acceptable granularity. Exposures of approximately 3 s are sufficient, and minimize the effect of the rocket precession, which results in a slow rotation of the focal plane of the coronagraphs.

In a separate compartment there is an extreme ultraviolet (XUV) heliograph[2]. This consists of an off-axis, normal incidence paraboloidal mirror of 25 cm focal length, which forms a direct solar image on Schumann-type SC–7 film. Aluminium film filters and a platinized mirror restrict the passband to 170–500 Å.

This letter describes the records from an Aerobee 150 rocket launched at 1930 UT on March 7, 1970, from White Sands Missile Range, New Mexico, approximately two hours after the total solar eclipse in Mexico. In particular, we wished to photograph the white light corona beyond 3 solar radii, where the corona in Earth-based photographs tends to fade into the background sky when atmospheric conditions are unfavourable. The flight could not be made simultaneous with the eclipse in Mexico because the Sun was partially eclipsed at the launch site at this time, and the full solar disk was required to make the solar pointing control of the rocket work properly.

Fig. 1 shows the coronagraph record from the flight, combined with a ground-based eclipse photograph to the proper scale, kindly supplied by G. Newkirk, jun.,

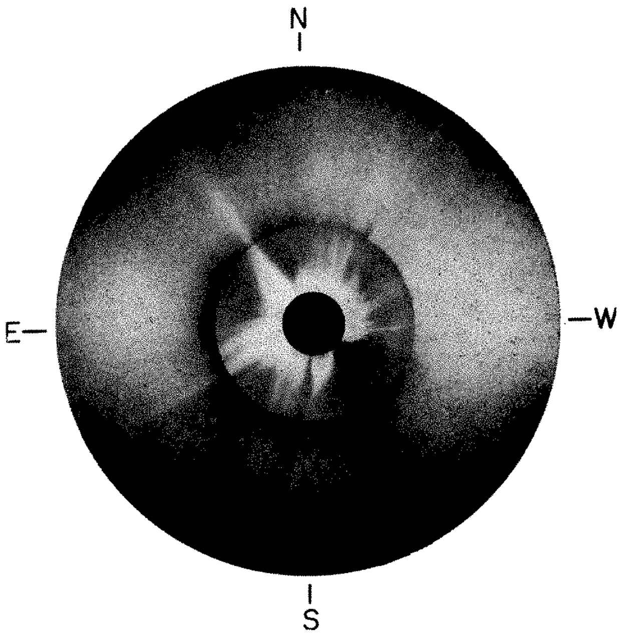

Fig. 1. White-light corona from the solar limb to 9 solar radii on March 7, 1970. The outer corona from 3 to 9 $R_\odot$ is from a pair of exposures made with the NRL coronagraph at 1930 UT. The inner corona was photographed in Mexico by G. A. Newkirk, jun., at approximately 1740 UT. In both the radial decrease in brightness has been compensated instrumentally to give a uniform exposure over the field.

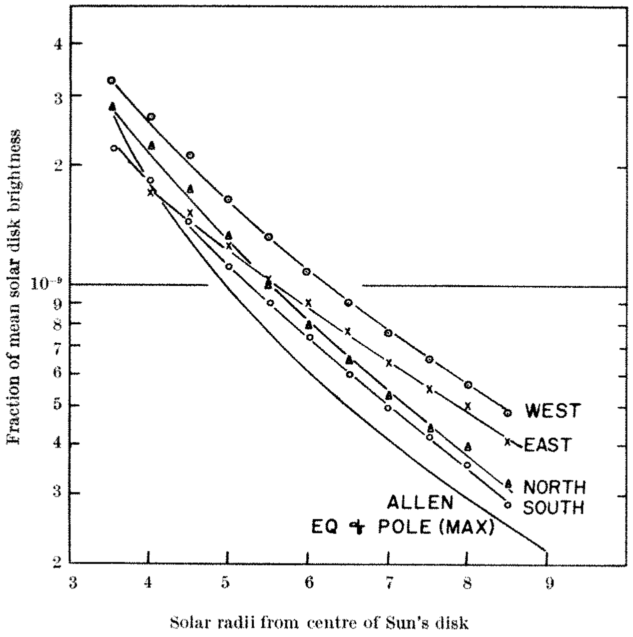

Fig. 2. Brightness of the K+F corona at the equator and poles on March 7, 1970, compared with data for solar maximum published by Allen.

director of the High Altitude Observatory of the University of Colorado. The field brightness in this composite appears nearly uniform because of the vignetting produced by the external occulting disk; the vignetting function compensates for the radial decrease in brightness of the corona. The dark arc to the east of the centre is the Moon silhouetted against the corona. The Newkirk photograph has better resolution than the rocket photograph, but is similar in that it was made with a filter which compensates for the radial decrease in coronal brightness. Our comments will be restricted to the outer picture taken with the rocket coronagraph.

The coronal streamers appear here as parallel or slightly diverging, with no detectable curvature. Therefore the range beyond 3 solar radii may not be greatly influenced by the complex magnetic fields nearer the limb. We call attention to the dark sector in the south-east, bounded sharply on one side by the strong south-east streamer, and more faintly on the other by a broad feature. The effect is probably produced by the projection of several different streamers on to the plane of the sky, but perhaps may indicate some peculiarity of the large scale magnetic field.

The rocket photograph does not show to any extent the dark sector in the south-west which is so strikingly evident in the Newkirk eclipse photograph. The darkening seems mostly associated with the region close to the limb. All streamers appear to lose contrast and disappear into the general coronal background as they approach the edge of the field at 9 radii. It is believed that the background is true corona rather than stray light.

Although it is difficult to estimate the contribution of instrumental stray light to the general background, the black appearance of the Moon suggests that stray light is negligibly small. The lunar image is at fog level in the original negatives. In this connexion it is interesting to note that sky conditions in Mexico were exceptionally good, and that streamers were recorded to elongations greater than the 9 $R_\odot$ limit of our coronagraph (private communication from Newkirk and Pasachoff). This is surprising if the stray light in our instrument is indeed small. Perhaps the ground-based films could detect a smaller difference in contrast than our film, but this was at least partly compensated by the contrast-reducing effect of residual skylight. Overall we would expect our film, which was developed to a gamma of 2·0, to have a contrast rendition comparing favourably with that of ground-based films.

Our photograph shows a prominent equatorial enhancement of the background corona. Again this seems real, with a negligible contribution from stray light as shown by the blackness of the lunar silhouette which lies in the equatorial plane, and by the fact that the original negatives showed the enhancement to be fixed in space during successive exposures while the coronagraph focal plane rotated some 60° due to the rocket motion.

The photographic advantages of the vignetted coronal image are ultimately neutralized by the increased care required in the photometry of the photograph, because film response is a strong function of the radial position in the field, and accurate measurements of position as well as density must be made on the 35 mm negative. Fig. 2 is a preliminary measurement of the equatorial and polar brightness. The data have been smoothed to some extent but include the local effects of the streamers. The curves show the equatorial enhancement, as well as the enhancement between 3 and 6 solar radii in the polar regions produced by the presence of streamers. The curve of brightness for equator and pole during solar maximum, as published by Allen[3], is included for comparison.

The two-hour difference between Newkirk's photograph and the rocket record has produced no obvious mismatch of streamers, but it is possible that small differences between our and other eclipse data may be found. On our negatives, the angle between the strong north-east and south-east streamers, projected back to their crossing point, is 82·7°. Other streamers are more diffuse and cannot be located with accuracy. We call attention to the group of three which lies to the west of north. The westernmost member of this group is 57·6° from the strong north-east streamer.

Fig. 3 shows successively longer exposures of the solar disk image, obtained with the rocket XUV heliograph. The most striking features are the corona-like emission above the limb and a narrow limb-brightened ring around the entire disk.

Purcell *et al.*[2] concluded on the basis of earlier spectroheliograms that the narrow limb was caused chiefly by Ne VII (465 Å), Mg IX (369 Å), and the progression Fe VIII at least to XI and perhaps to Fe XIV. The XUV corona, projected beyond the limb, was contributed to by all these lines, but was produced especially by the very high-stage ions of Si, Mg, and Fe, to stage XVI. Thomson scattering of solar disk radiation was ruled out as a possible mechanism because the emission was far too intense relative to the disk. It therefore seemed likely that the radiation was produced by collisional excitation of the ions by free electrons, especially in the low corona where the electron density is high. This mechanism makes the intensity proportional to the square of the electron density and will produce a steep radial gradient in the XUV corona. The gradient was actually observed to be shallow, and there was no structure corresponding to white light streamers, even in the outer XUV corona which was recorded beyond 2 $R_\odot$ in the long-exposure heliograms. It was therefore proposed that this corona was caused by resonance as well as collisional excitation, and that the unexpectedly great intensity was associated with a high abundance of Fe ions in the corona.

Whatever the relative importance of the emission mechanisms, the low XUV corona observed on March 7, 1970, has a considerable resemblance to the low white-light corona photographed on the same date. This is shown in Fig. 4, where one of the XUV images of Fig. 3 has been masked with a disk of black paper to show only the features projected beyond the limb. This is compared with a short-exposure eclipse photograph from the US east coast one hour earlier. One difference is that the XUV corona has depressions not seen in the white light corona.

We have noticed in several previous XUV disk photographs that limb brightening is suppressed in the neighbourhood of Hα limb prominences. In Fig. 4 the depressions also seem to occur near the positions of Hα limb features.

Although the long-exposure heliograms of Fig. 3 do not reveal any structure which may be imagined to correspond to a white light streamer, we do not consider that the absence of XUV streamers has been adequately proved. Our long-exposure heliograms have all suffered to some

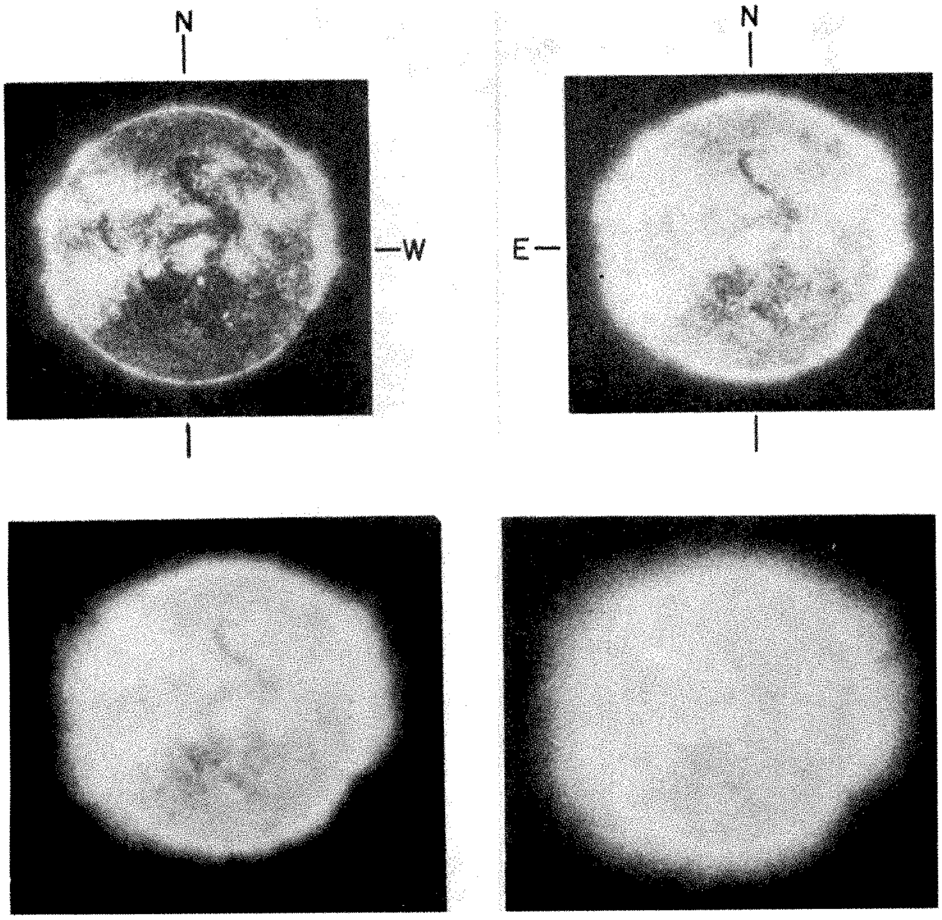

Fig. 3. The solar disk in the band 170–500 Å photographed with successively longer exposures to record the corona. March 7, 1970, 1930 UT.

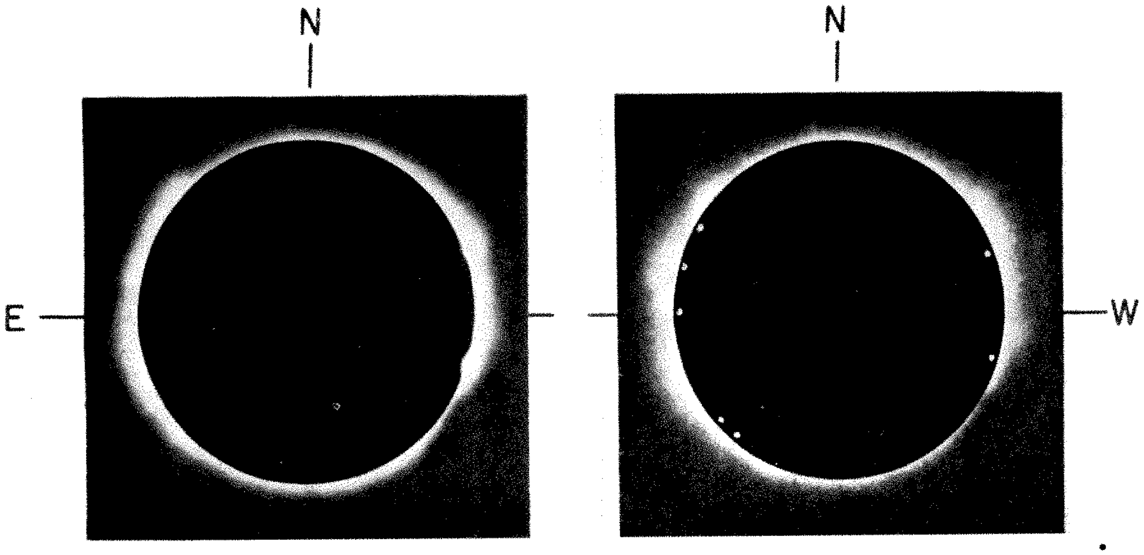

Fig. 4. A short-exposure white light eclipse photograph (left) taken at 1835 UT, compared with an XUV heliogram from Fig. 3. The heliogram is masked to show only the emission beyond the limb. Approximate positions of Hα limb features are indicated on the mask by white dots.

extent from image rotation produced by rocket precession. This may have masked any streamers. We hope eventually to make long exposures in a three-axis stabilized system free of image rotation. It is desirable also to have the Moon in the field of view as in Fig. 1 as an indicator of instrumental stray light.

We thank the National Aeronautics and Space Administration which has supported this and many previous rocket coronagraph experiments. Mr Robert Krupinski of this laboratory made the short-exposure eclipse photograph in Fig. 4. We also thank Mr R. T. Seal, Mr C. B. Snyder, and Mr R. K. Chaimson for help. The coronagraph optical system was designed and manufactured by Tropel Inc., and the rocket pointing control was manufactured and operated by the University of Colorado.

The Lockheed-Aerospace Eclipse Expedition

We used highly portable equipment which could be set up on almost any surface, and left the decision on the location of the observing site as late as possible so as to take advantage of the latest weather forecasts. Our range of possible sites included all points along the path of totality between Tallahasee, Florida, and Norfolk, Virginia. We flew into Atlanta, Georgia, about 32 hours before totality, and a weather assessment there encouraged us to fly to Norfolk where a final decision was made to motor south-west into North Carolina. The final site selection was made on the morning of the eclipse, and we observed from a farm near Beargrass.

Four coronal photographic experiments were carried out. The first, conceived by H. E. Ramsey of Lockheed, used an $f/12$ plane polarizing telescope of 24-inch focal length to observe the coronal green line at 5303 Å. The filter loaned by Spectrolab had a passband of 1 Å at 5303 Å, and we used Kodak 103 AG film. Exposures were made at four polarizing positions 45° apart, and a fifth (off band) exposure was made in the nearby blue continuum by tilting the filter. Fig. 1 is typical of the on-band exposures. Visual comparison of the four photographs shows no important intensity differences.

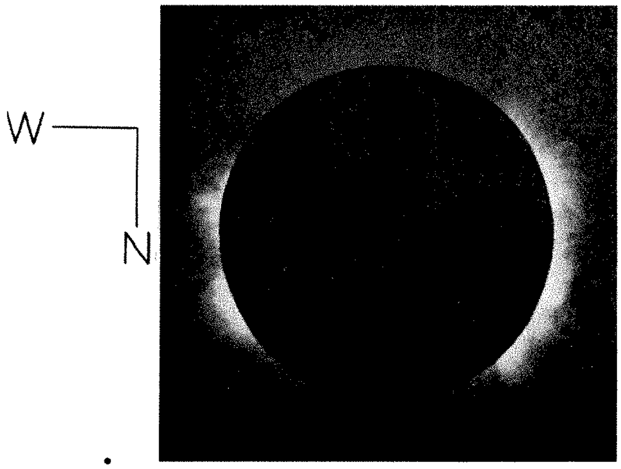

Fig. 1. The green line corona.

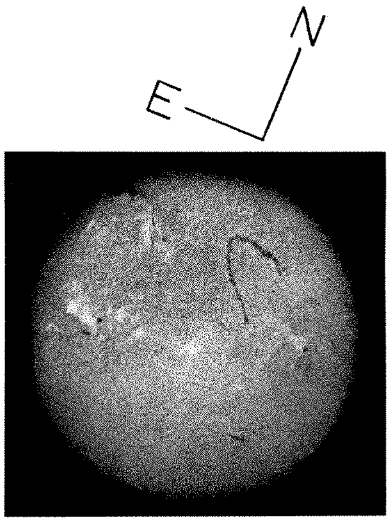

Fig. 2. The solar disk at the time of the eclipse photographed in the light of Hα (Lockheed Solar Observatory, Saugus, California).

The chief value of the green line photographs is in the study of coronal rays, arches, and other structural detail. We have found a close correspondence in the general appearance of the green line corona with the white light corona although our white light photographs do not show nearly as much structural detail. Further comparison of the green line pictures with higher resolution photographs in white light taken by Sheldon Smith of NASA Ames Research Center shows an even greater similarity in the form and structure of the corona. No structures are visible in the green line that are not also visible in Smith's white light photographs showing more extensive detail. We feel certain of the reality of the structure at 5303 Å because an exposure of equivalent length taken with the 5303 Å filter tuned approximately 2 Å into the blue wing of the line reveals only a narrow, irregular band of corona around the limb with no structural detail.

The green line structure is sparse at the poles and pronounced in the active regions. A system of closed coronal arches is visible in the NW quadrant of Fig. 1 (upper right). We have found that other systems of loops intermingled with the ray structure on the east and west limbs can be identified in the original negatives through high contrast printing.

The largest of the prominences visible during the eclipse is an extension of the large filament on the NE quadrant of the solar disk seen in Hα light in Fig. 2. The filament (or prominence) is in the northern part of the active region zone and does not seem to be associated uniquely with any particular loop system in the inner corona. In the white light photographs of Sheldon Smith, however, the outer corona reveals an extensive helmet and streamer above this prominence as well as above the prominences on the SW and NW limb. On the SW limb, the northern end of a loop prominence seems to terminate in a very tiny active region. This region began developing on the solar disk on the preceding day around 1700 UT. During the eclipse a very small flare and corresponding small surge occurred in this active region from about 1733 to 1741 UT. The active region lies just within the southern boundary of the active region zone. The green line corona above the region is not intense although the region is situated almost exactly on the limb. Apparently the green line exposure is so short that it reveals only the base of the helmet structure and streamers over this active zone. Above the small prominence on the NW limb, however, concentric arches within the helmet can be seen in the green line photographs as well as in Sheldon Smith's white light photographs.

Another camera used aero infrared Ektachrome to obtain pictures of the corona. Exposure times were from 32 s to 1/60 s with a Wratten No. 12 filter. Streamers can be seen out to nearly five solar radii on the 4 s exposure. In general, the structures agree well with those seen on the normal colour film, but the radial density gradient on the infrared film seems to be somewhat lower. Properly exposed regions, outside the white aureole, show a deepening blue with increasing radius.

A third instrument using a 680 mm focal length solid catadioptic objective (loaned by Boller and Chivens) and a camera with an automatic film transporting mechanism (loaned by EPOI West) was devoted to white light colour photography of the entire eclipse. These photographs include the diamond ring effect, Baily's beads, prominences, and exposures showing the inner corona and outer corona to a distance of 2·3 solar radii.

Broad-band Hα pictures of high contrast were taken for details of the coronal ray structure. A graduated series of exposures were taken on a four-inch Questar telescope with a 250 Å passband filter centred at 6563 Å, using Kodak SO-375 film.

Swiss Solar Eclipse Expedition to Mexico

THE Swiss expedition was split into two groups operating at Nejapa and at Miahuatlán to carry out a programme of photometric, polarimetric and spectroscopic observations of the solar corona (Figs. 1 and 2). We also obtained motion pictures of the eclipse and colour photographs of the corona for educational purposes.

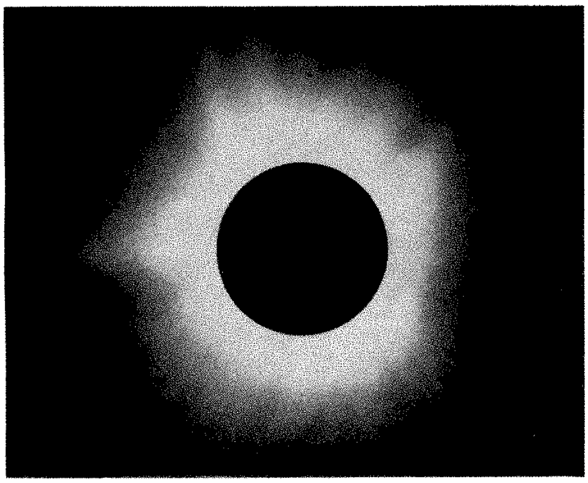

Fig. 1. The streamers of the outer corona. The axis runs from upper right (south) to lower left. The picture was taken using a one-mirror coelostat, so east is at upper left.

For more than thirty years I have been observing the coronal emission lines at the Arosa observatory, but the coronagraphic method is restricted to the relatively bright innermost corona. Even the brightest line, the green line at 5303 Å, can hardly be observed at more than 6′ from the limb. The excitation of this line can be by photospheric radiation as well as by electron collisions, and to separate the contributions of these two mechanisms the line intensity has to be observed to much larger distances than can be reached with coronagraphs. To do this we used a low dispersion spectrograph of high luminosity, which could be rotated about the axis of its collimator so that the radial distribution of the intensity of the green line could be measured at sixteen different position angles and out to about one solar radius from the limb. The spectrograph was built for the green line, but it gives the whole spectrum from 3900 to 6500 Å.

A thorough knowledge of the electron density is needed for the interpretation of the line intensities and their variations. This was achieved by observing the distribution of the white light of the corona, using two cameras of focal length 120 cm and 150 cm. The white light is photospheric light scattered by free electrons and the photometric measurements can easily be transformed into electron densities.

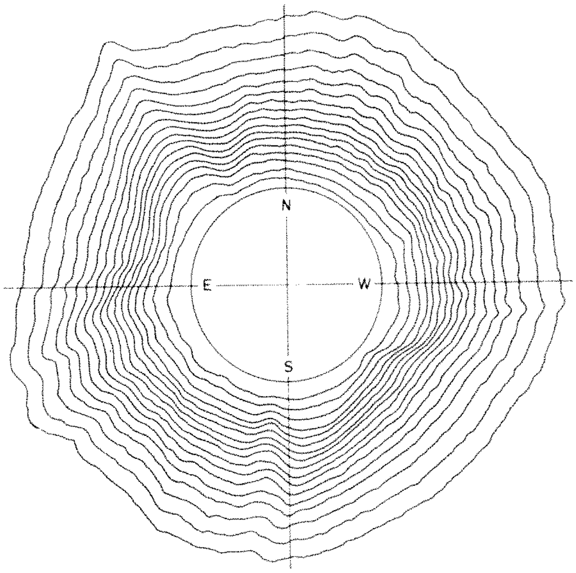

Fig. 2. Isophotes of the corona. There is no appreciable flattening. The most conspicuous feature is the long and isolated streamer in the NE-quadrant. The weakest part of the corona is found in the SW-quadrant, and a pronounced dark rift is seen near the S-pole.

The corona is not a homogeneous atmosphere, but consists of a multitude of individual streamers again built up of finer details which are visible on pictures of high resolution. We used a camera of 8 m focal length which shows only the inner parts of the corona, but it is in the innermost regions where the corona shows the finest and most fascinating structures, especially over centres of activity. These structures are formed by magnetic fields emanating from deeper layers. This is the only way to get an insight into the shape of the magnetic fields in the immediate surroundings of the Sun.

The theory of scattering predicts strong polarization of the white light of the corona. The degree of polarization depends considerably on the angle of scattering, and a streamer the axis of which is perpendicular to the line of sight shows stronger polarization than one with a smaller inclination. It is only by polarimetric measurements that the inclination of the streamers to the line of sight can be determined, and an extensive programme of

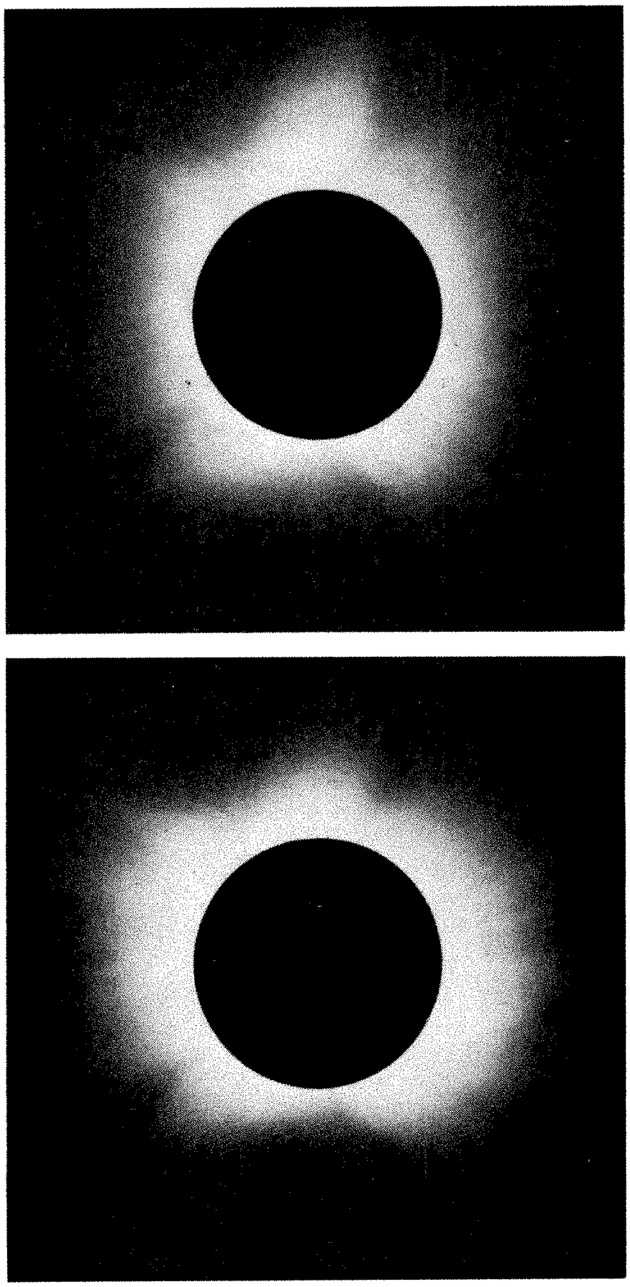

Fig. 3. Two pictures of the corona in linearly polarized light. In the upper picture the direction of polarization is vertical, in the lower picture horizontal. The axis runs from upper right (north) to lower left (south). East is at upper left.

polarimetric measurements was carried out using a camera of 120 cm focal length (Fig. 3).

Los Alamos Airborne Observations

THE eclipse of March 7, 1970, was observed off the east coast of Mexico from an Air Force NC-135A instrumented by the US Atomic Energy Commission for chromospheric, coronal, and geophysical observations.

The proper intercept flight path was calculated from Bessel elements of the eclipse from the 1970 *American Ephemeris and Nautical Almanac*. The equipment was built to view the eclipse (63° altitude) at an azimuth of 100° relative to the aircraft nose, so the no-wind aircraft path needed to be 5° to the left of the totality path for a west coast intercept and 13° to the right (53°·3 true) for the actual east coast intercept. The true altitude of the aircraft was 36,380 feet. The actual ground speed of 508 knots and ground track of heading of 53°·7 true give a duration of 5 min 39 s (using an effective Δt = ephemeris time minus universal time = 40 s). The actual duration measured was 5 min 30 s, two minutes more than the 3 min 28 s expected on the ground.

The nine seconds discrepancy between the predicted and measured durations can be due to a number of effects such as navigation errors, inaccurate Bessel elements, or to the kilometre or more uncertainty in the actual lunar radius at both the second and third contact points.

A practice mission from Kelly Air Force Base was flown on March 4 at the west coast intercept. The navigation proved to be somewhat more difficult at that location, and the proximity of the ground observers prevented the continuation of the track (with possible contrails) to the east for calibrations after the eclipse. Therefore even though totality lasted a few seconds longer at this site, the east coast intercept was chosen because of advantages of higher altitude possible at a shorter range from the base, easier navigation, and the possibility of a long post-eclipse calibration track. A second post-eclipse calibration run of ten minutes was made on the way home after last contact on both rehearsal and eclipse days.

The chromospheric and coronal observations were all made by instruments with combinations of gyro and photoelectric tracking. Hydraulic power was used to maintain the pointing of the heavier instruments instead of electric motors. Photographs with the equipment of highest resolution, a coronal camera, had pointing errors of less than 10 s of arc.

The coronal camera had an *f*/6 lens of 610 mm focal length with three cemented doublets. The electronic computing machine lens had its best focus between 5000 Å and 7000 Å where the photographs were made. The automatic control system enabled C. F. Keller to record sixty-eight photographs in various polarization planes on Kodak 2475 film with exposure times ranging from 0·01 to 10 s. The unusually spiky appearance of the active corona was recorded out to thirteen radii from the solar centre.

Lower resolution photographs were taken with an emission line camera by R. Engleman and R. E. Partridge. Nine 13-inch *f*/6 lenses produced images on a single sheet of Kodak 2475 film with a patch of Kodak high speed infrared film. The forbidden emission lines observed, with half widths of the filters between 3 and 5 Å, were: 5303 Å (Fe XIV), 5303 Å (Fe XIV) with polaroid, 6374 Å (Fe X), 5694 Å (Ca XV), 7892 Å (Fe XIII), and 5890 Å (Na I). Background photographs were taken at 6426 Å, 5357 Å, 5277 Å. Three good exposures, of 27, 27 and 105 s, were obtained. Photometry will show the structure of the corona for the various emission lines.

A Fourier transform infrared spectrometer was used by K. H. Olsen and C. R. Anderson to measure the chromospheric and coronal spectra in a circular spot of 10 min of arc at both the second and third contact points. With a resolution of $2\ \text{cm}^{-1}$ the spectrum, including the emission lines of Si X, He I, H I, and others not yet identified, was recorded with an InSb detector at wavelengths between one and three microns.

An *f*/8 telescope of eighty-inch focal length was used by M. M. Hoffman and D. H. Liebenberg to record the line shape of the green and red iron lines in the corona. Narrow band optical line filters were used in front of a Fabry–Perot interferometer, and the varying freon gas pressure gave a spectral scan of the selected emission line at every point in the coronal image. The fringe pattern was recorded with a high resolution image orthicon video camera coupled to a video tape recorder. The data will be analysed for line shapes and coronal temperatures.

The behaviour of the 5577 Å and 6300 Å forbidden neutral oxygen emission lines and the 3914 Å N_2^+ emission line from the Earth's upper atmosphere was also recorded along paths through and in the lunar umbral shadow by M. M. Robertson and J. H. Wolcott. Scans between the lunar direction and 30° from the horizon in the direction perpendicular to the umbral path were made to study excitation mechanisms for this airglow when the solar light is rapidly cut off. Recorded intensities were very close to those expected from previous airglow measurements.

Photometric Study of the Solar Corona

ON March 7, 1970, we observed the K and F solar corona photographically at El Gramel, Oaxaca, Mexico. The technique has already been explained[1,2], but has been improved since the 1968 experiment in Siberia. By using a graded filter—the neutral radial attenuator technique—photographs were obtained in E-radial and E-tangential polarized light which allow the polarization of the fine structure in the electronic corona to be evaluated. Thus the F corona as well as structures in the K electronic corona can be subject to precise photometry on correctly exposed photographs. Overexposed parts cannot be avoided using the traditional photographic methods (Figs. 1–4).

Photographs in natural light were obtained through a window in the attenuator, to give an indication of the conditions of the observations. It seems that for practical purposes the centre of the Moon was not affected either by the atmospheric diffused light or by instrumental light.

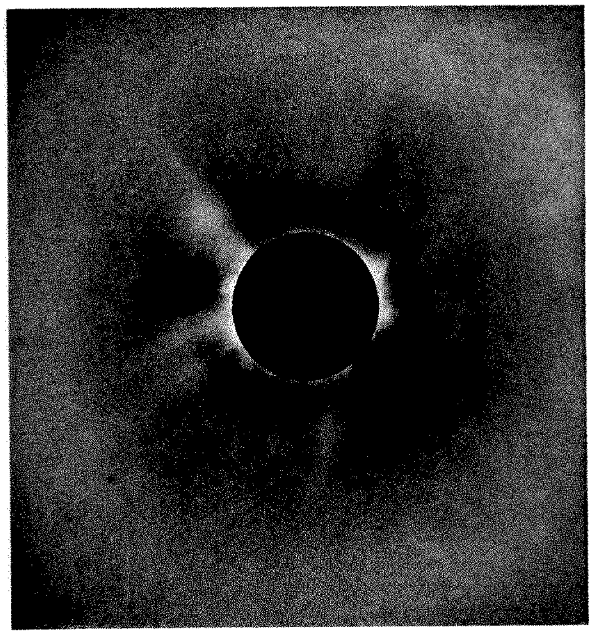

Fig. 2. The same photograph in radial polarized light.

This offers exceptional conditions for observing the solar corona. In particular, it is possible to neglect completely for $\rho > 2$ the influence of the coronal aureole, the sky brightness being the result of double diffusion[3]. It is interesting to note also that the diffusion of solar radiation by illuminated particles situated outside the shadow, and possibly between the Moon and the Earth, is not observed[4] as it is in rocket experiments.

Thus an excellent morphological study of the electronic corona is possible. The filament structure is evident and the dispersion of the intensities of the various streamers as well as their superposition shows that the slide registers a large range of streamers situated in quite distinct planes. The "dark filaments" reported in 1968 (ref. 5) were again observed (Fig. 3). It seems impossible, *a priori*, to interpret these structures as "holes" in the corona (the traditional interpretation for the coronal cavities).

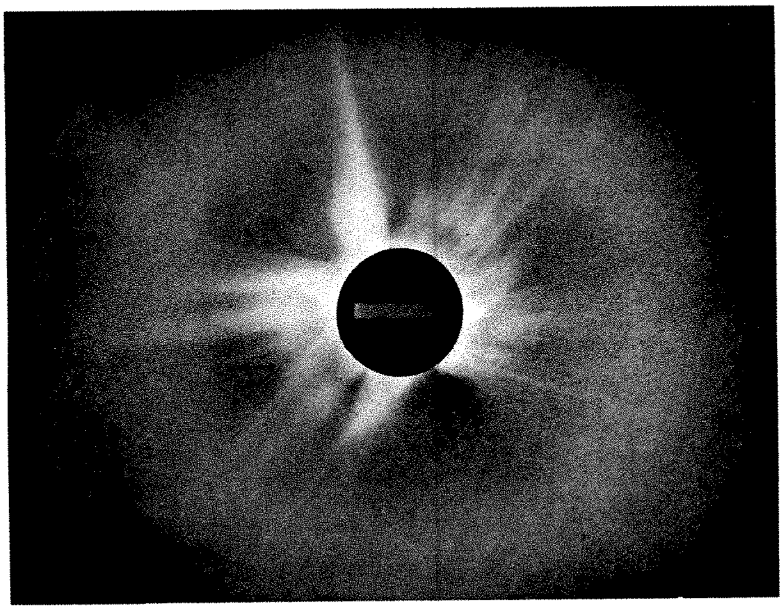

Fig. 1. Photograph of the solar corona at $\lambda = 5700 \pm 200$ Å, on March 7, 1970, 1735 UT. A rectangular window on the Moon registers the Earthshine.

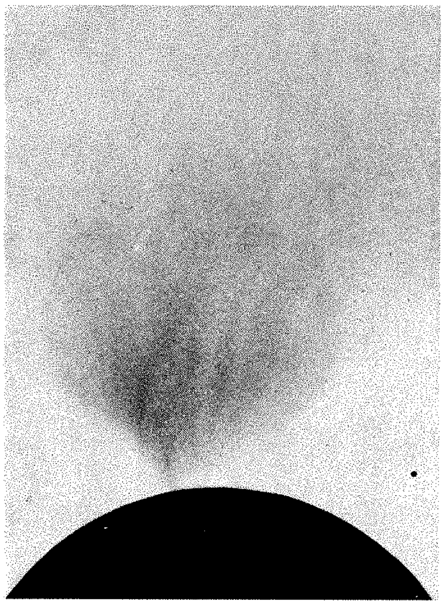

Fig. 3. Enlargement showing two "dark filaments" in the corona.

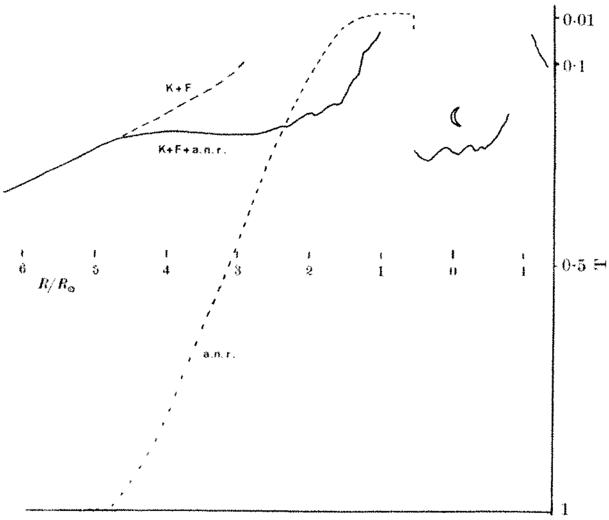

Fig. 4. Radial microphotometer tracings on the natural light half of the slide. The details of the Earthshine on the Moon are obtained quantitatively. The dashed line represents the tracing of the neutral radial attenuator.

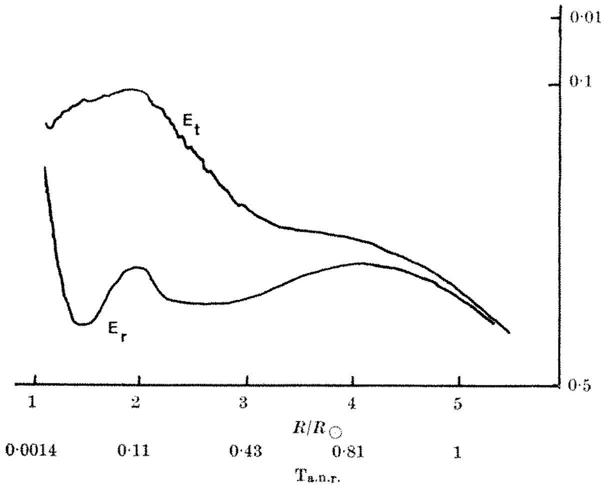

Fig. 5. Radial microphotometer tracings in radial (E_r) and tangential (E_t) polarized light, showing the variation of the polarization with $\varrho = R/R_\odot$.

The variation of the polarization rate in solar polar coordinates is given by simple photometric scanning, along the same radius, of two E-tangential and radial polarized photographs without any intermediate calculation. Two of these scans are presented in Fig. 5, which shows that the polarization rate increases rapidly from the limb to a maximum value at $\rho \sim 1{\cdot}4$ and then decreases because of the growing importance of the non-polarized F corona.

We thank Dr Michard for discussions.

Doppler Temperature of the Solar Corona

WE have observed the thirteen-times ionized line of iron in the solar corona, Fe XIV $3p^2P_{1/2}$–$^2P_{3/2}$ at $\lambda = 5302{\cdot}86$ Å. This was done with Fabry–Perot interferometers both photographically and using a photomultiplier. The results are still preliminary, but we already have information on the Doppler temperature and motion of the corona as far out as 1·85 solar radii.

In contrast to previous observations[1], we find that the corona is in violent motion, as shown by definite spectral shifts and differences in Doppler temperature.

The photographic Fabry–Perot interferometer was placed with horizontal plates in an invar mounting which was temperature controlled to within ±1° C. The light was collected by a 10 inch diameter coelostat with a lens of focal length 145 inches. The 5303 Å line was separated with a $2\frac{1}{2} \times 2\frac{1}{2}$ inch interference filter placed near the primary focus. The light was made parallel by an auxiliary lens so that the image of the Sun and the Fabry-Perot fringes would be focused together by the camera. A K-37 aerial camera with a 12 inch lens used at *f*/7 formed the final image of the interferometer fringes and the corona together on a special Eastman Kodak 2485 high speed recording sheet film. The Fabry–Perot was equipped with Baird Atomic dielectric multilayer coatings which afforded an overall finesse of 14, yielding an instrumental half-intensity width of 0·2 Å with a plate separation of 0·05 cm.

The exposures used, 5, 15 and 60 s, were long enough to provide fringes extending to large distances from the Sun.

The photoelectric Fabry–Perot was swept with Freon-12 pressure and was also mounted in an invar case. The signal was chopped, received by a refrigerated EMI photomultiplier and was amplified by a PAR phase sensitive amplifier. The apparatus was mounted on an equatorial mount originally designed for an 8 inch reflecting telescope.

Microdensitometer tracings, made radially from the centre of the fringe system, which was at a point 0·2 solar radii from the limb on the north-west side, were first reduced to intensities using a calibration exposure developed with the plates. We corrected for the background due to the continuum by assuming an exponential decrease fitted to the intensities read between fringes. The corrected Fabry–Perot pattern thus obtained gives line shapes and wavelength shifts without complications arising from the very steep intensity gradient of the corona.

Preliminary results indicate that the half intensity width of the green coronal line during this eclipse varied between

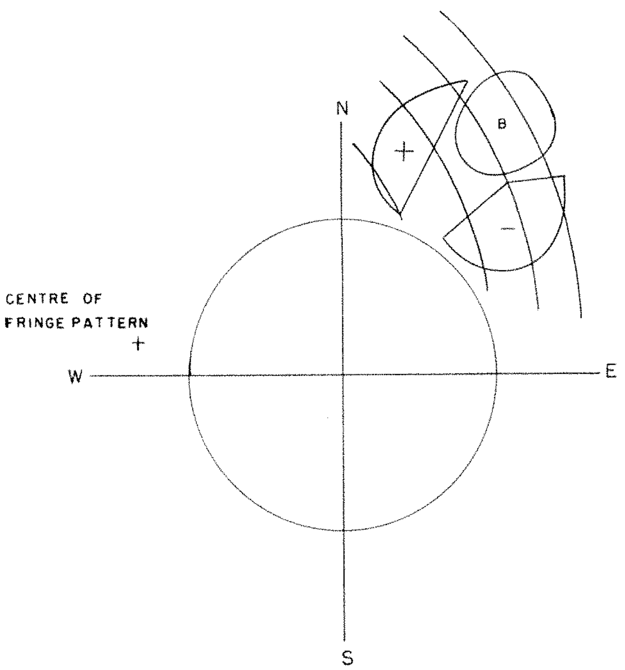

Fig. 1. Position of principal wavelength shifts and broadening of the 5303 Å line, and position of the fringe pattern. The region indicated by + has the line shifted toward longer wavelength and the region indicated by − the opposite. Region B corresponds to a decrease of intensity and a broadening of the line.

0·8 and 1·1 Å and that the intensity distribution was definitely unequal, with large intensities in the southern hemisphere and in an active area which extended up to 1·8 solar radii toward the north-east. This active area corresponds to the prominence and the strong arches and fan rays observed in this region[2], and seems of particular interest because of the large variations of width and the wavelength shifts associated with it. These variations seem to be restricted to definite localities corresponding to the arches in the white corona (Fig. 1).

The connexion between the prominences, the coronal streamers and the emission corona has long been believed to determine the structure of the corona[3]. Our preliminary results, as shown in Fig. 1, would reinforce this suggestion because they indicate a cooler fan system slowly rotating around a hotter and less dense plasma. We are studying the possibility of relating the wavelength shifts to the broadening of the line. Such a relationship could show a correlation between motion in the corona and the temperature and perhaps give a clue to the heating mechanism.

The Outer Corona at the Eclipse of March 7, 1970

Light from the vicinity of the corona at total solar eclipses may come from five possible sources: (1) the E-corona of emission lines; (2) the K-corona, a partially polarized continuum scattered by free coronal electrons; (3) the F-corona, whose Fraunhofer spectrum is usually regarded as the central part of the zodiacal light-radiation scattered by interplanetary dust; (4) superposed light from the sky, ordinarily caused by multiple scattering from distant regions in partial eclipse; (5) scattered light within the instrument superposed on the final image.

Models of the solar corona depend markedly on the evaluation of the relative contributions from sources (3), (4) and (5). The most widely accepted model of the corona is that proposed by Van de Hulst[1] and updated by Blackwell and Petford[2], for which the intensity of the F-corona exceeds that of the K-corona beyond radii, measured from the centre of the Sun, exceeding about 2·2 for sunspot maximum. Preliminary results from our expedition to Miahuatlan, Oaxaca, Mexico, indicate that the K-corona may be dominant at much greater distances from the Sun than had been thought previously.

To separate the F- and K-coronas we carried out four kinds of experiments, from which data are now being reduced. First, a new spectrograph designed by J. G. Baker registered the coronal spectrum from 3500 to 6000 Å. Second, four television cameras recording on videotape scanned the corona over a field of 5 × 7 solar diameters, with rotating polaroids and different neutral and coloured filters, an experiment designed by W. W. Salisbury and D. L. Fernald. Third, we photographed the coronal polarization. Fourth, we photographed the corona with a variety of different lenses, as in Fig. 1.

During the eclipse the sky was exceptionally clear and Rayleigh blue to the edge of the solar disk. This condition was particularly favourable for observing the corona. To the naked eye, the corona appeared stellated, with long streamers plainly visible to four or five solar diameters. These structures would ordinarily have been obscured if any haze had been present. They also showed clearly on long-exposure calibrated photographs. Two of them, located at position angles 12° and 94°, extended

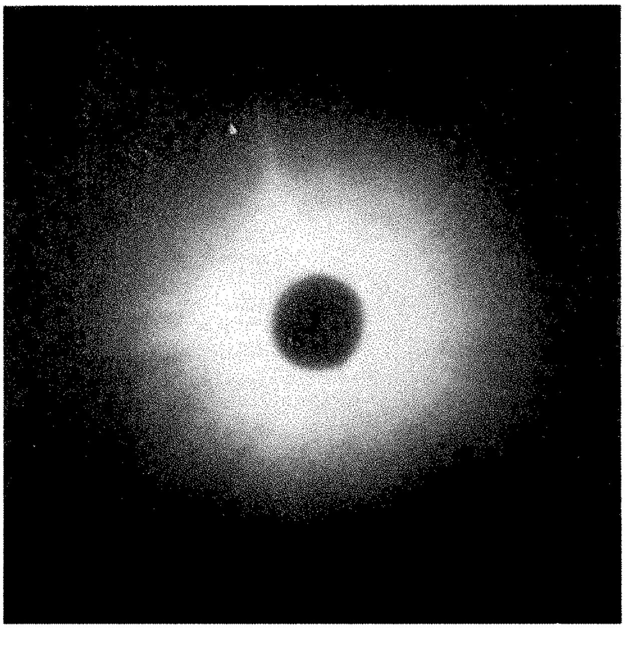

Fig. 1. Our calibrated photographs of the outer corona show streamers extending beyond 10 solar radii. This print, which shows more structure in the medium corona, is one of a series with stepped exposures.

out to at least 10 solar radii from the limb. They were long and straight, apparently unaffected by the curvature that solar rotation might induce. They also exhibited strong polarization.

Because the F-corona should be symmetrical around the limb, structureless and unpolarized, the character of these streamers and many other shorter rays indicates that they comprise the K-corona. Their polarization also supports this conclusion.

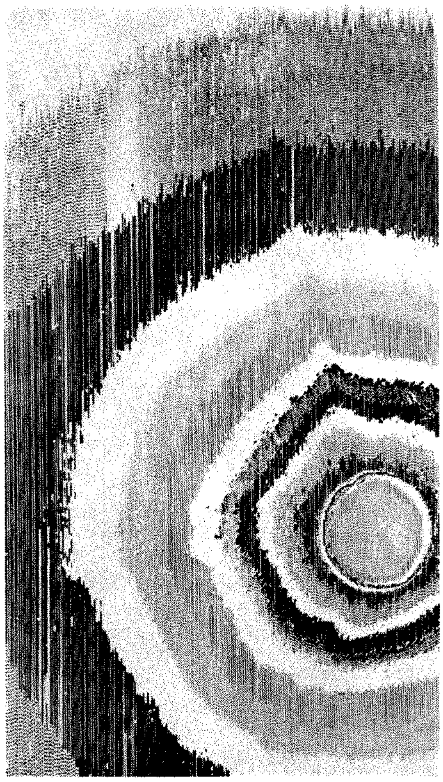

Fig. 2. Preliminary isophotes for the eclipse of March 7, 1970. Each change in the output of the isodensitracer—dashes to dots, dots to blank, and so on—corresponds to a change of 0·2 in photographic density.

Preliminary photometry of the records indicates that the streamers, however prominent they may seem to the eye, represent only slight increases of photographic density. Although the isophotes are not at all circular on Fig. 2 out to at least four radii, the streamers show up only as slight projections. This result indicates that they decrease in intensity away from the Sun at approximately the same rate as the overall coronal radiation. According to theory, the F-corona should decrease more slowly than the K-corona, so we conclude that inner zodiacal light does not contribute appreciably to the corona out to distances of at least 10 solar radii. As for ground-based observations of the Fraunhofer spectrum of the outer corona reported for previous eclipses, we suggest that it may well derive from cause (4): superposed skylight. To test this point, the slit of our spectrograph was long enough to cross the entire solar disk, so that any sky spectrum from the Moon's silhouette could be used for calibration.

The expedition was sponsored by the Harvard College Observatory, Smithsonian Astrophysical Observatory, National Geographic Society, Air Force Cambridge Research Laboratories, National Science Foundation, Videonics, Inc., and friends of the Harvard College Observatory. Other members of the expedition included F. A. Budreski, A. S. Clarke, D. L. Fernald, J. R. Hamilton, L. A. Lief, M. Mattei, J. Pitts, D. H. Read, F. de Romaña and W. W. Salisbury.

Variations in Line Profiles from Photosphere to Chromosphere

WE observed from Miahuatlan (Oaxaca), Mexico, near the centre line of totality. A high-resolution Littrow-type grating spectrograph, fed by a coelostat and an objective lens (25 cm, 340 cm), was provided at second contact with a slit 12 μm wide, slanting through the last crescent of the solar photosphere and the chromosphere. The slit was removed before third contact.

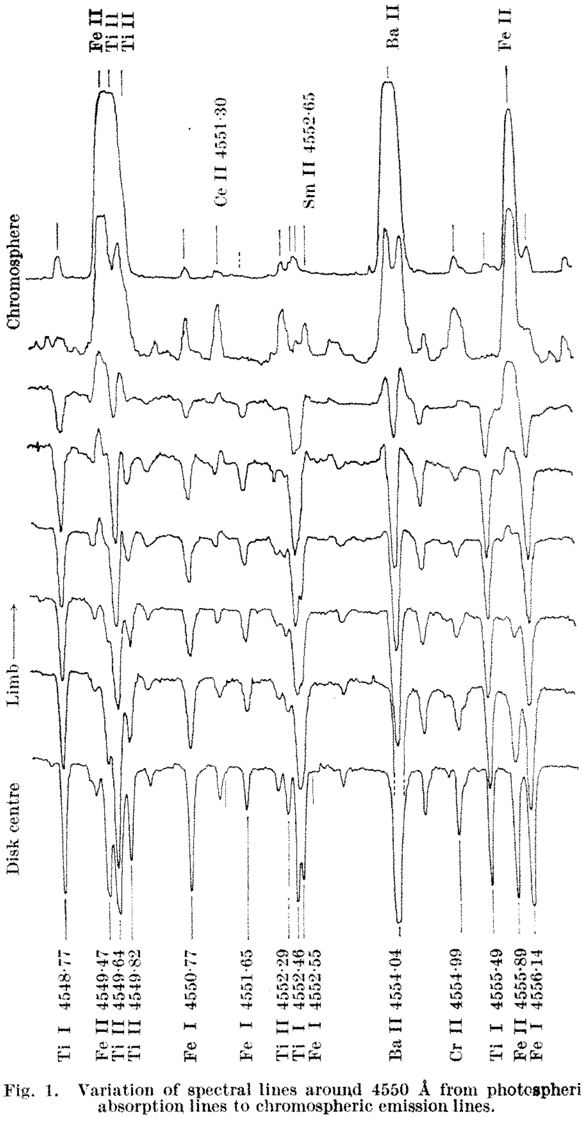

Fig. 1. Variation of spectral lines around 4550 Å from photospheric absorption lines to chromospheric emission lines.

We photographed the region from 4545 Å to 4579 Å simultaneously on two 70 mm films with respective intensities of 8 and 90 per cent, using a beam splitter, at a dispersion of 1·7 mm Å^{-1}. A shutter was guided photoelectrically in order to obtain the proper exposure times. Before and after the eclipse we took calibration spectra of the central part of the solar disk. In addition to this in the same spectrograph the region of the Mg b lines near 5200 Å was focused on a multiplex chopper and the coded spectrum was recorded on magnetic tape. This part of the experiment was developed by Th. de Graauw.

We made provisional microphotometric records in transmission of the photographic spectra at second contact. Because of differences in photographic densities and the adjustment of the photometer, the records show only qualitative differences in the appearance of spectral lines of different atomic and ionic origin in the transition from photosphere to chromosphere (see Fig. 1).

The extensive reduction of these spectra, using the laser-determined instrumental profile, the slit-jaw films and event-timing and time signal tapes, will take some time and the reduction of the multiplex tape has not yet started. Eventually we hope to obtain true line profiles of the outer limb and the transition region to the chromosphere.

We thank Drs C. de Jager and C. Zwaan for discussions and Messrs J. W. van den Broek and H. J. van Amerongen for help with the experiment. The expedition was supported by the Netherlands Organization for the Advancement of Pure Research (Z.W.O.).

Association of Coronal Structures with Chromospheric Structure

SIX direct photographs of the total phase of the solar eclipse of March 7, 1970, were made at Sandbridge, Virginia (longitude 75·9161° W, latitude 36·6759° N, mid-totality 1836 UT), using an achromatic doublet of focal length 7·62 m and Eastman Kodak Tri-X orthochromatic sheet film. This note describes the coronal structures and their apparent relationship to chromospheric features observed in Hα and CaII K at the McMath-Hulbert Observatory (Table 1). We use the terminology suggested by Newkirk[1]; position angles are measured (accuracy ±3°) eastward from the pole of rotation; McMath plage numbers designate active centres; longitudes of disk features are given relative to the central meridian of the Sun.

Fig. 1 shows one of the photographs, and a schematic sketch locating the more significant features is presented in Fig. 2. Table 1 lists those coronal features most prominent on our photographs and their probable association with activity in the chromosphere. The quoted position angles of streamers are the positions of intersection of their axes with the limb.

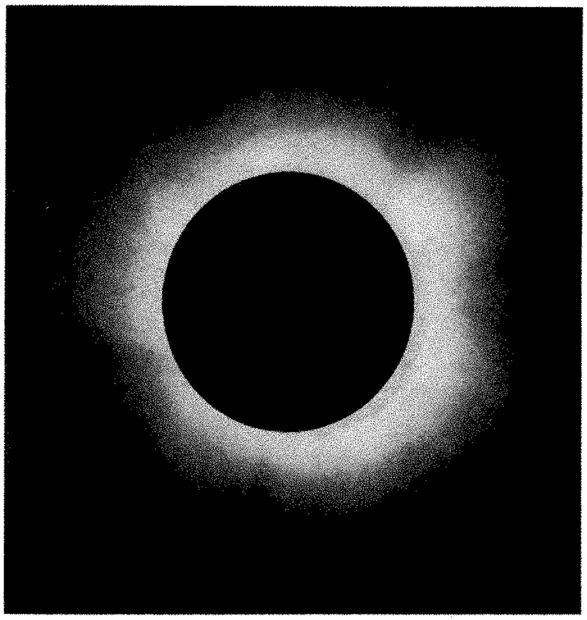

Fig. 1. This 20 s exposure beginning at 18 h 37 m 06 s UT was taken at f/30. Heliographic north is approximately at the top and east is to the right (see Fig. 2).

Especially noteworthy is the position angle of the cleft directly in the south and the decided difference in the appearance of coronal structure within about 30° (P.A.) of each pole. The western and northern parts of the corona, from P.A. 228° to P.A. 20° seem to be constituted predominantly of fine filamentary details (narrow rays) while the eastern and southern regions tend to be less filamentary and smoother in appearance. Streamers are without exception tilted poleward, towards the nearest pole, by varying amounts, contrary to the sense of tilt of streamers at minimum solar activity[2].

The maximum dimensions of the arches given in Table 1 are as estimated on our photographs. Such features have a subtle appearance in white light on low-contrast emulsions and are of somewhat uncertain extent. The arches at P.A. 30° and 190° are only partially visible on our photographs, and the quoted positions refer to the approximate centres of the arches as if they were complete.

An Hα filtroheliogram taken at 1631 UT is shown in Fig. 3 to aid in identification of structures on the visible

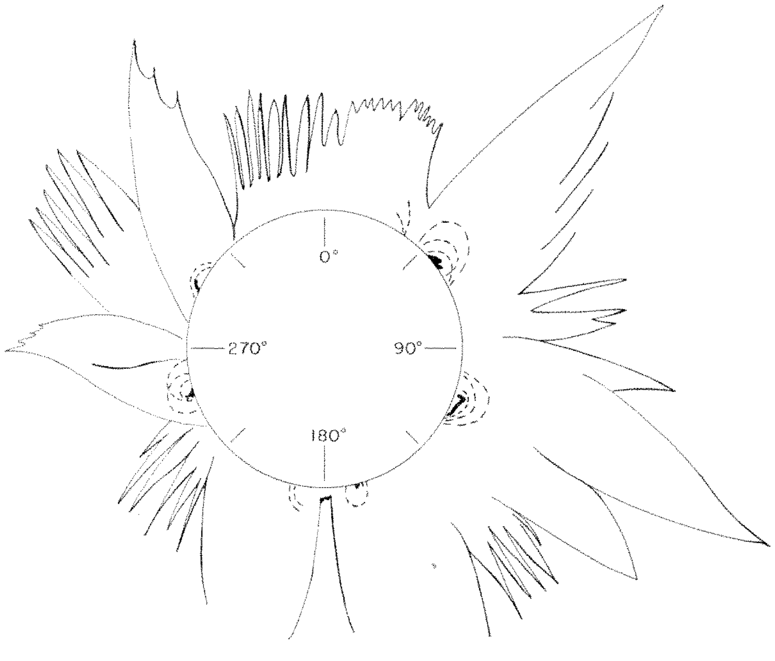

Fig. 2. The principal features shown on direct photographs are located in this sketch. Position angles are measured eastward from the north pole of rotation. Regions in which narrow rays were predominant are only schematic.

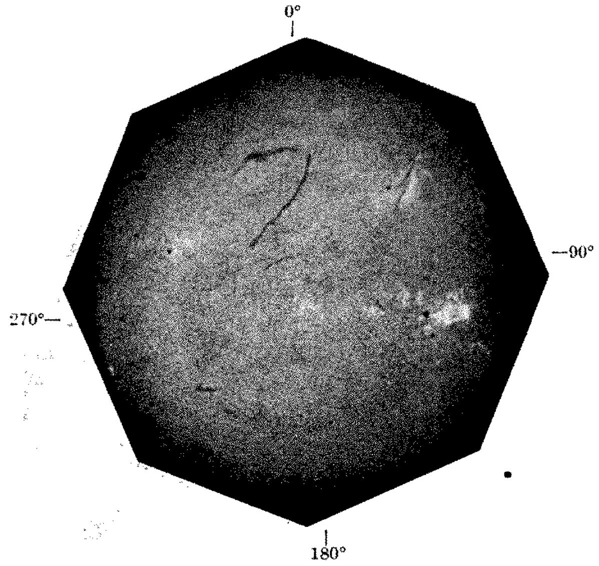

Fig. 3. This Hα filtroheliogram was taken at the McMath–Hulbert Observatory at 16 h 31 m UT. An imp. 1 flare was in progress in plage 10618 (S 14° E 42°). Cardinal directions on the Sun are given relative to the poles of rotation. The north pole was tilted 7·25° away from the Earth.

disk. Trending generally north-eastward from plage 10617 on the visible hemisphere is an extensive, well-developed filament which passes across the limb as a prominence near P.A. 54°. The major helmet streamer and arches near P.A. 50°–52° are associated with the plage or, more likely, with the prominence and filament. Observations on March 8, 9 and 13 show that behind the limb the filament jutted northward to at least P.A. 35°. It is possible that the amorphous portion of the northern "plume zone" near P.A. 20°–36° is associated with the north-eastern extension of the prominence. Hα filtroheliograms made on March 8 and 9, however, show the presence of a small high-latitude filament in the north-east which would have been on or close to the limb near P.A. 30° on the eclipse day. It may have been associated with the (partial ?) arches at that position angle.

Significant flaring activity occurred on March 7, 1970. Six subflares were reported in the plage on the south-west limb, No. 10621 (S 19°, W 80°) between 0 h and 18 h 30 m. Two 1N flares were reported after our time of totality. This plage formed on the previous day and a small spot was seen in it on March 7. A prominence at P.A. 250° is undoubtedly associated with this region. Above the prominence but not concentric with it is a system of arches, enclosed within a compact streamer that does not have a helmet-like appearance. Very extended, curving narrow rays meet the limb at position angles within the compact dome-like streamer. The plage region was not seen when the heliographic position which it occupied on March 7 next rounded the east limb, however. It is also possible that the compact coronal streamer is associated with plages 10602 (S 14°, W 80°) and 10604 (S 03°, W 70°).

On the day before the eclipse, March 6, a proton flare may have taken place behind the west limb. An eruptive bright surge was seen at P.A. 282°, beginning at 0926 UT, accompanied by a large 10 cm radio burst and followed by a loop prominence display and the detection of 20–70 MeV protons in space near the Earth. On our photographs the region of the corona near the position angle of the bright surge is confused, apparently consisting of a weak streamer on which narrow rays are superposed.

Table 1. POSITIONS AND DESCRIPTIONS OF CORONAL STRUCTURES

P.A.	Feature	Remarks
		Polar regions
330°–36°	Northern plumes	Rays very long and narrow. Somewhat amorphous in P.A. 20°–36°.
30°	Arches (partial ?)	Height ~3·4′ arc. No prominence within.
147°–228°	Southern streamers	Each has arches at base.
168°	Arches	Height ~2·3′ arc. Small prominence at base ?
180°	Cleft	6° broad at limb.
190°	Arches (partial ?)	Height ~2·4′ arc. No prom. within. Associated south-western streamer may be related to filament extending SE from plage 10584 (S 15° W 173°) nearly to limb in P.A. ~225°.
		Lower latitude regions
50°	Major helmet streamer	Associated with plage 10617 (N 19° E 30°) or with filament extending NE from it. Arches and prom. within. Axis is tilted 11° northward from radial direction.
52°	Arches	Height ~5·5′ arc. Width at base 22° P.A. Not concentric, not centred on prom. at P.A. 54°.
54°	Prominence	Extremely long prom. trending across NE limb.
83°	Streamer ?	A weak streamer may be present with a small prom. at its base at P.A. 79°.
94°	Streamer	No arches or prom. at base. Tilted 22° southward from radial. May be associated with plage 10618 (S 14° E 42°).
114°	Arches	Height ~3·9′ arc. Width at base 22° P.A. Higher arches not concentric, lowest arch centred over prom. at P.A. 116°.
120°	Streamer	Not well-defined. No arches or prom. within. Tilted 11° southward of radial. May be associated with plage 10629 (S 16° E 116°) and prom.
135°	Narrow rays	Prom. at base in P.A. 140°, no arches. Tilted 14° southward of radial.
230°	Narrow rays	The boundaries of this region in which there is an absence of bright streamers curve strongly away to north and south.
255°	Arches	Height ~2·9′ arc. Width at base 22° P.A. Higher arches not concentric; lowest arch centred over prom. at P.A. 250° in plage 10621 (S 19° W 80°). This is a new plage.
263°	Streamer	A compact streamer. Extended curving rays reach limb within base cf this streamer.
281°	Weak streamer with superposed narrow rays ?	Not well-defined. No arches or prom. at base. The structures appear generally to be tilted 32° northward of radial. See text.
300°	Arches	Height ~1·6′ arc. Width at base 12° P.A. These are concentric on P.A. 300°. A small prom. at P.A. 297° completes the southern arm of the inner arch. At location of plage 10598 (N 29° W 97°).
304°	Streamer	Tilted 39° northward of radial. May be associated with plage 10595 (N 16° W 110°) and/or with plage 10592 (N 18° W 137°) and/or with plage 10598 (N 29° W 97°).

The two most prominent features on our photographs are the major helmet streamer at P.A. 50°, already discussed, and the bright structure near P.A. 290°–300°, just north of the bright surge of the previous day. The latter is apparently part of the southern edge of a streamer seen superposed with other structures and the axis of which meets the lunar limb in P.A. 304°. There are three possible plage candidates for the chromospheric origin of this strongly tilted (39°) streamer (see Table 1).

Photospheric Magnetic Fields on March 7, 1970

DAILY magnetograms were obtained at Kitt Peak beginning two weeks before and concluding two weeks after the eclipse. Initiated by Dr Gordon Newkirk[1], the aim of this programme was to produce a synoptic map of solar magnetism from which the potential field configuration might be inferred for comparison with observed coronal features (see Fig. 1). These results will be reported elsewhere by

Newkirk. A side product was the production of full disk magnetograms having a resolution of 2–3 arc s and a good response to a wide range of field intensity including that of sunspots. A new instrument, the 40-channel magnetograph, was available for these observations. In this note we present a magnetogram for the eclipse day (for comparison with other disk phenomena) and also magnetograms taken approximately one week before and after the eclipse day. The latter may be of some value for the interpretation of limb observations although the evolutionary change with time makes any comparison inexact.

The 40-channel system is essentially a forty-fold expansion of the Babcock magnetograph[2]. The 80 cm image of the McMath telescope is scanned in a TV raster pattern across the entrance slit of the spectrograph. In front of this slit is the usual electro-optic analyser for circularly polarized light. At the spectrograph focus a fibre optic probe dissects the spectral image of the wings of Fe 5233 Å, perpendicular to dispersion, into forty adjacent elements of 1 mm. Light is conducted from the probe to an array of eighty photomultiplier tubes which are followed by associated amplifiers and phase-locked detectors. Magnetic and brightness signals are recorded on magnetic tape. A full disk magnetogram, consisting of $\sim 6 \times 10^5$ elements, requires forty-five minutes to run.

Figs. 2, 3 and 4 show the magnetic data as intensity maps drawn by the computer. Positive fields are shaded light, neutral fields are grey and negative fields are dark. The response of the magnetograph to **B** cosγ is linear to ±2 per cent from 0 to 4,000 G. For these maps the relation between exposure *E* and **B** cosγ is given by

$$|\mathbf{B}\cos\gamma| < 10\ \mathrm{G},\ E = 56\ \text{(arbitrary units)}$$
$$-10\ \mathrm{G} > \mathbf{B}\cos\gamma \geq -2{,}000\ \mathrm{G},\ E = -108\ (\mathbf{B}\cos\gamma)^{-0.286}$$
$$+10\ \mathrm{G} < \mathbf{B}\cos\gamma \leq +2{,}000\ \mathrm{G},\ E = 29\ (\mathbf{B}\cos\gamma)^{+0.286}$$

Thus the weak fields are emphasized and a peak field

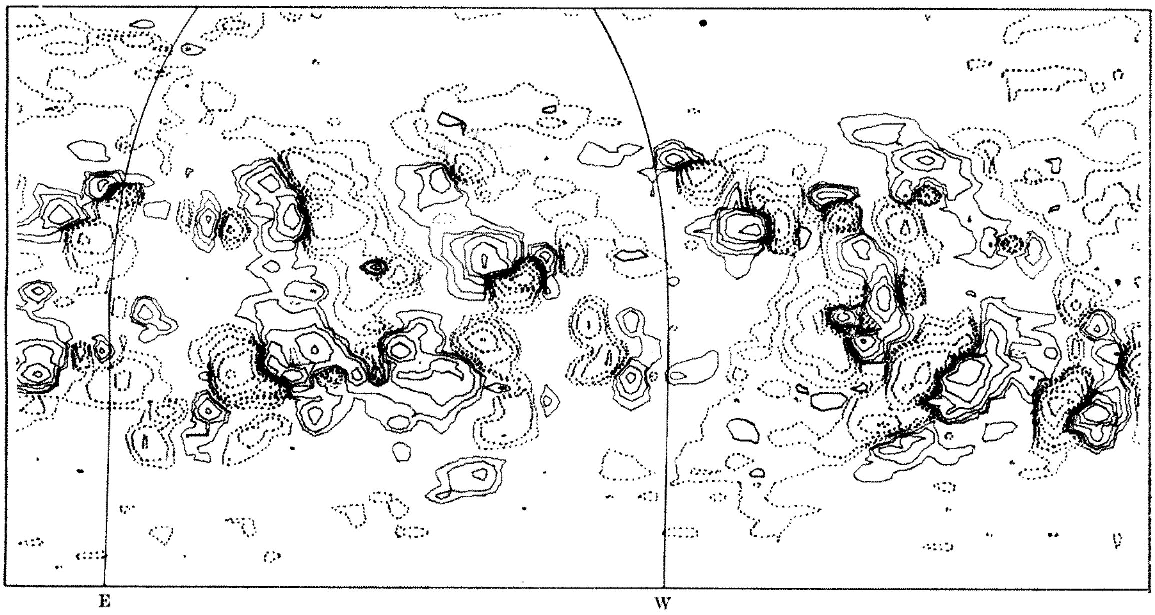

Fig. 1. Synoptic map of the average line of sight component of the magnetic field centred on the epoch of March 7, 1970. Solid and dashed contours enclose positive and negative magnetic flux respectively. North is at the top and east is to the left. The position of the limb at the time of the eclipse is indicated. The contours are drawn for values of ±4, 8, 16, 32, 64 and 128 G averaged over areas of 0·0417 in sine latitude and 6·6° in longitude.

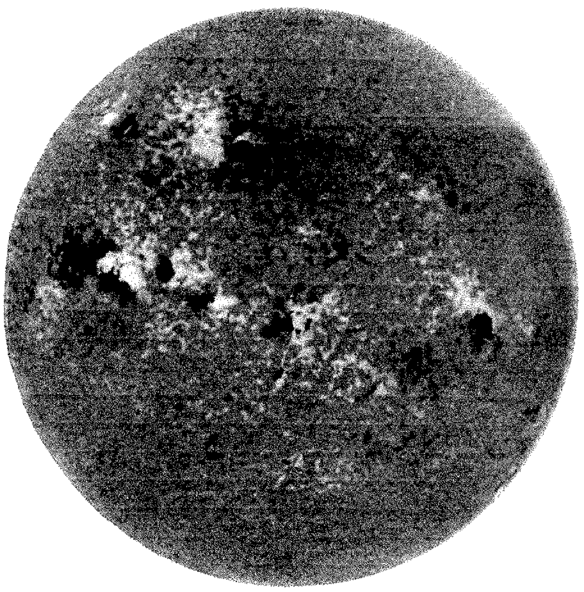

Fig. 2. Magnetogram for March 7, 1970 (2058 UT). Geocentric north is at top, west at the right. Ranging from bright to dark the steps are 2,000, 620, 200, 55, 14, −29, −110, −290, −750, and −2,000 G.

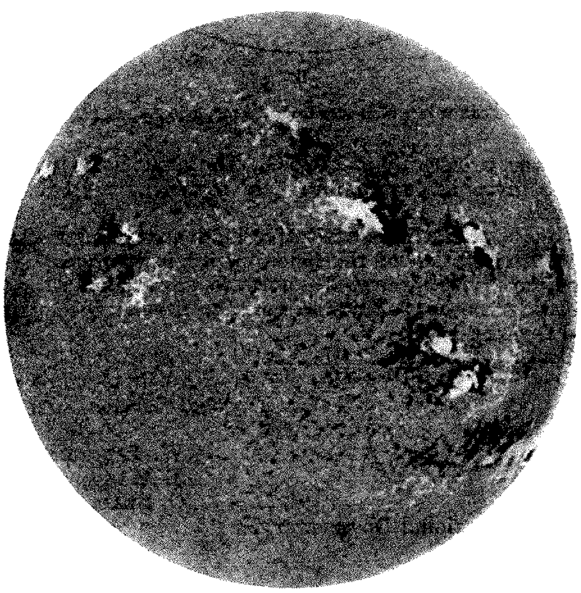

Fig. 3. Magnetogram for February 27, 1970 (1514 UT).

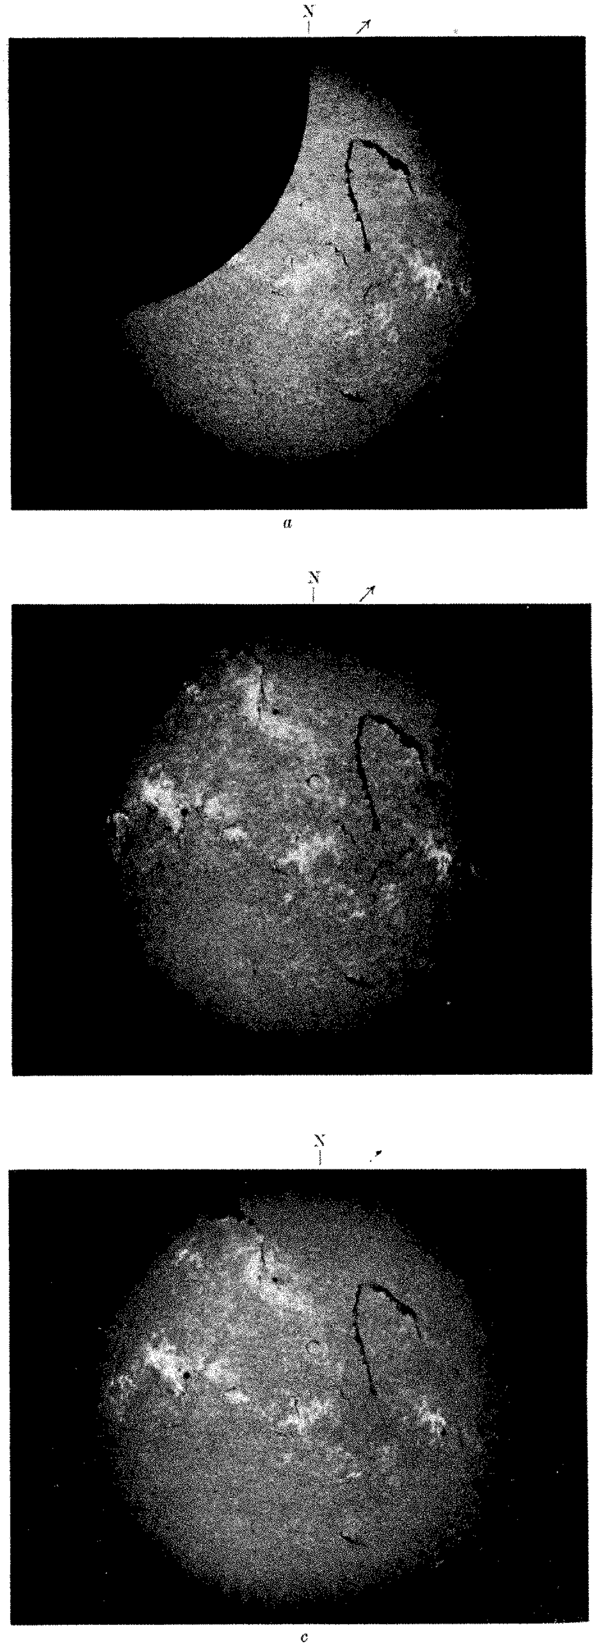
Hα Filtergrams of the Sun on March 7, 1970

We obtained a series of Hα filtergrams of the Sun between 1835 and 1950 UT, during and subsequent to the eclipse.



a

c

Fig. 1. *a*, and *c*, Hα filtergrams during the eclipse of March 7, 1970. Arrows show the direction of the axis of rotation of the Sun.

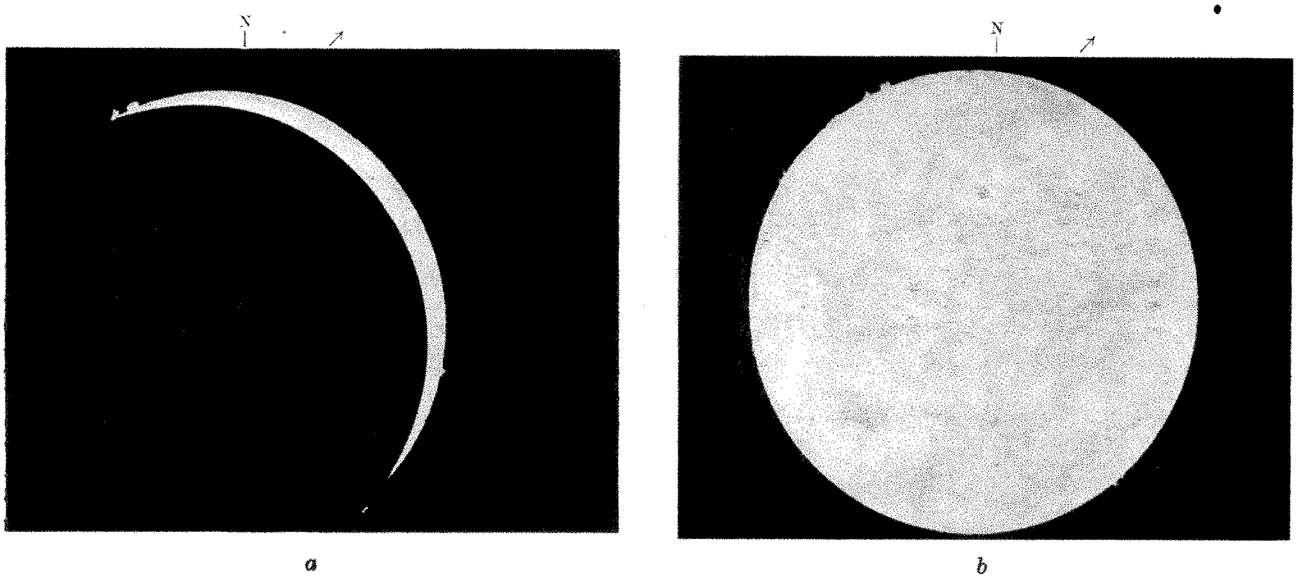


Fig. 2. *a* and *b*, Over-exposed Hα filtergrams during the eclipse of March 7, 1970. Notice the prominence beyond the limb of the Moon in the lower right side of Fig. 2*a*.

Although our observatory near Greenbelt, Maryland, was not in the path of totality, the photographs will be useful to others in interpreting observations of the eclipsed Sun.

The filtergrams were taken on Eastman SO-392 solar recording film with a Zeiss telescope of 96-inch focal length and a 0·5 Å Halle interference filter[1].

Figs. 1*a*, 1*b* and 2*a* show filtergrams during several phases of the eclipse. Figs. 1*c* and 2*b* are filtergrams made just after the fourth contact of the eclipse. Filtergrams 2*a* and *b* are over-exposed in order to show prominences. The bright plage area near the SW limb is particularly interesting, and this region at W 82° S 22° (region 72) was the site of a 1 N flare at 2120 UT (ref. 2). There were also several subflares and considerable surge activity associated with this region before, during and after the eclipse. A prominence that was possibly associated with this bright plage is shown clearly in Fig. 2. In Fig. 2*a* the Moon is still occulting the limb of the Sun, but the prominence is already visible.

A 1 B flare and a 1 N flare occurred at 1127 and 1607 UT respectively in another plage area at E 36° S 14° (region 87).

A striking filament, apparently greater than 500,000 km in length projected on the disk, is seen in Fig. 1.

Observations at the Sagamore Hill Solar Radio Observatory

THE solar eclipse of March 7, 1970, was observed at the Sagamore Hill Solar Radio Observatory, Hamilton, Massachusetts, with all the equipment normally used in the solar radio patrol[1]. The Sun was monitored with radiometric receiving equipment and associated antennas at frequencies of 114, 245, 606, 1,415, 2,695, 4,995, 8,800, 15,400 and 35,000 MHz. This is the first time that an eclipse has been observed at one site with such an array of equipment managed by one organization, with benefits in data consistency between frequencies, reliability and accuracy of calibration. At the site the eclipse was 96·2 per cent total.

Solar eclipses are still the best and least expensive means of studying certain characteristics of solar emission. This is especially true in the radio domain where a number of parameters can be studied which relate to the distribution of radio brightness across and beyond the disk. Several dozen eclipses have been observed by radio astronomers in the previous twenty-five years[2], and the emphasis at present is on solar predictions and beyond that, explanation and prediction of ionospheric activity.

This letter discusses the radio spectrum and history of one active region, McMath 607. We also consider the residual emission at eclipse maximum and discuss these spectral data in terms of changes in the solar spectrum during the sunspot cycle.

The eclipsing action of the Moon provides a resolution in one dimension which cannot be approached by even the newest and most sensitive interferometers. The extent, intensity and spectra of regions can be determined from eclipse occultation curves (Fig. 1) or more precisely from the derivative of the occultation curves.

Region No. 607 at about N 7°, W 26° early on March 7 was only one of four or five significant regions on the disk on that day. Regions 617 and 618 on the eastern part of the disk were considerably more complex and will be analysed in detail in a later paper. Region 607, however, was somewhat isolated and lends itself to unambiguous resolution during both the covering and uncovering. From February 27, when the region first appeared near the east limb until it disappeared on March 11 beyond the west limb, its potential for producing important flare-bursts diminished greatly. The day-to-day development of the region is shown in Table 1. Although the plage continued to increase in area during passage across the disk, the sunspot area and magnetic configurations were evolving into smaller and less important classes. Many subflares and a few major flares with associated radio bursts were observed in the early days of the passage. The optical flare-radio burst correlation also continued to weaken with passage across the disk.

It is not known what its flux spectrum was on those days, although we suspect that it favoured shorter wave-

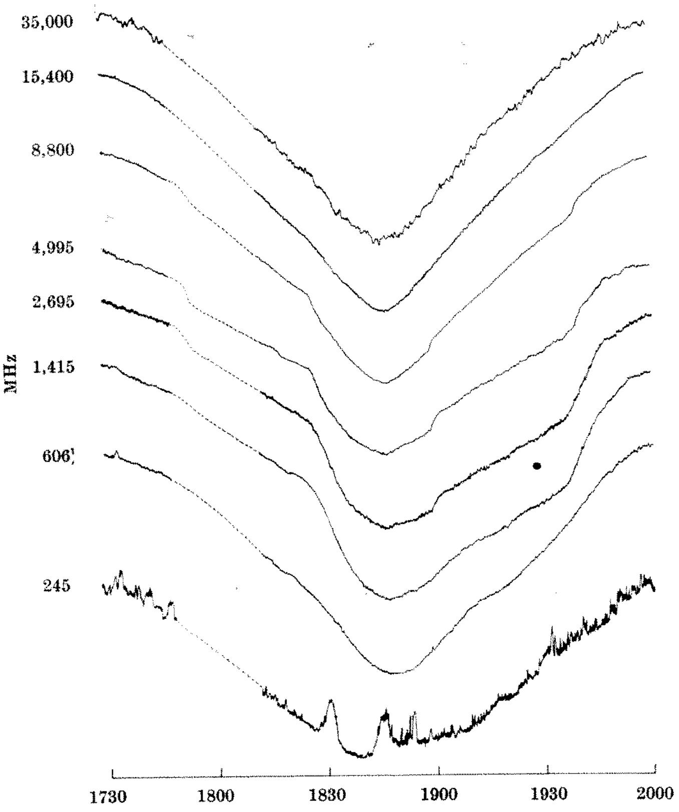

Fig. 1. Tracing of eclipse curves showing the covering and uncovering of strong sources of the slowly varying component of radio emission.

lengths. By March 7, the 9·1 cm brightness temperature had diminished greatly from its condition between March 1–5, 1970. The geomagnetic field, however, which became disturbed at 05/0805Z was probably related to the central meridian passage of this region.

The percentage changes in flux per minute of time caused by occultation of the radio source overlaying McMath Plage No. 607 are shown in Fig. 2 for the sources of wavelength 21·2, 11·1, 5·0, 4·29, and 3·4 cm for both the covering (ingress) and uncovering (egress) phases of the eclipse. Slope values are negative for the ingress and positive for the egress. The dashed lines indicate the slope values that would be obtained by eclipsing the background level of the Sun. To compress the figure, the ordinate values are arranged so that the zero level for the 11·1 cm curve is at the $-2·0$ level of the 21·2 cm curve, and so on for the other curves.

It can be seen that the changes in flux are more sharply defined and less extended in time, or dimension, during the uncovering of the source than during its covering. Optically the underlying plage and sunspot regions were rather extended longitudinally. The east–west extent of the spots was about 11° with the major spot group at the far west of the other spots in the group and at the western edge of the plage of 17° longitudinal extent. Because of this asymmetry of the optical region and the different geometry of the lunar limb during covering and uncovering, the non-symmetrical effects noted on the slope curves could be expected. But one effect that was not expected was that the shorter wavelength sources would be occulted first. Usually for a source with a radial height distribution as a function of wavelength located on the western sector of the Sun (the main spot group was at N 6° and W 26°), the longer wavelengths and thus the highest and most westerly sources would be eclipsed first. The same would be true for the egress where the longest wavelengths would be uncovered first. The slope curves for this region, however, show exactly the opposite. This apparent non-radial distribution could be accounted for by a shifting of the centre of gravity of the longer wavelength sources toward the east. These sources would then be more aligned with the centre of gravity of the plage.

Table 2. DIMENSIONS OF THE RADIO SOURCE ASSOCIATED WITH MCMATH PLAGE 607

By measuring the time between half-power points of the region slopes and multiplying this by the average lunar velocity factor of 26·6 s of arc per minute of time, the source dimensions can be estimated. Table 2 shows the average dimensions from ingress and egress.

These sizes are small, probably because of the association of the source with the isolated alpha spot group. The dimensions at 21·2 cm are difficult to obtain from the slope records because of the low flux levels at this wavelength, but by extending the egress curve several minutes beyond 1905 UT, it was possible to see a suggestive drop of the slope to the quiet background. In any case, the dimension of 3·1 min has a possible uncertainty of ± 1 min.

Flux densities for the region at the various wavelengths were obtained by integrating the area under the curves. The resultant values in flux units (1 flux unit $= 1 \times 10^{-22}$ W m^{-2} Hz^{-1}) for the ingress curves, the egress curves, and for the averages of the two are given in Table 3.

Table 3. FLUX DENSITIES IN FLUX UNITS FOR NO. 607

Wavelength (cm)	3·4	4·3	6·0	11·1	21·2
Ingress	7·0	11·5	10·9	8·0	?
Egress	7·9	10·3	10·8	7·2	4·1 ?
Average	7·5	10·9	10·9	7·6	4·1 ?

The spectrum and low intensity of this source precluded its being resolved at all frequencies monitored. The flux values for the source are also shown in Fig. 3. The spectral curve resembles those of strong sources where the magnetic field introduces resonance absorption at harmonics of the gyromagnetic frequency[3-5].

Brightness temperatures for the region were determined from the measured flux values and the source sizes. Although some asymmetry in source distribution was observed, we assumed a circular distribution because of the apparent smallness of the sources and for simplicity of computation. Using the expression

$$T_b = \frac{3283\ F\ \lambda^2}{2k\ \Omega}$$

where F = source flux in W m^{-2} Hz^{-1}, λ = wavelength in metres, $k = 1{\cdot}38 \times 10^{-23}$ J (degree K)$^{-1}$ and Ω = source extent in square degrees, the brightness temperatures of Table 4 were obtained.

The brightness temperature at 21·2 cm may possibly be low because of errors in the flux, and especially the size at this wavelength. For example, if the source size had been 2·0′ arc, the brightness temperature would have been $2{\cdot}5 \times 10^6$ K.

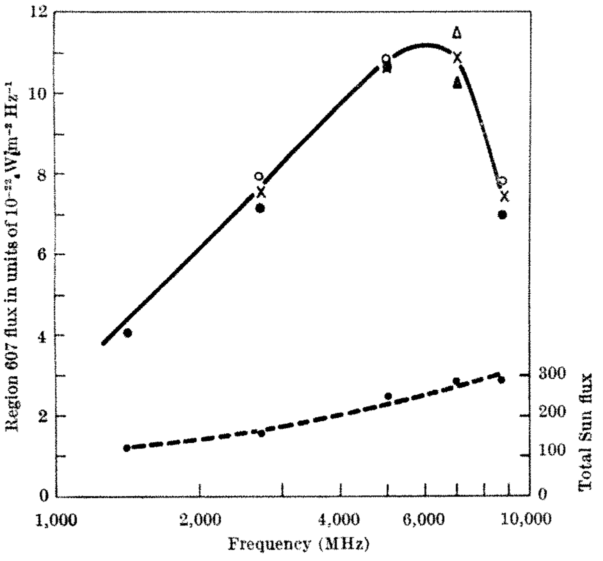

Fig. 3. Flux associated with McMath region 607. ○, Ingress values; ●, egress values; ×, averages; △, ▲, 4·29 cm data obtained by a group from Mackenzie University, São Paulo, Brazil.

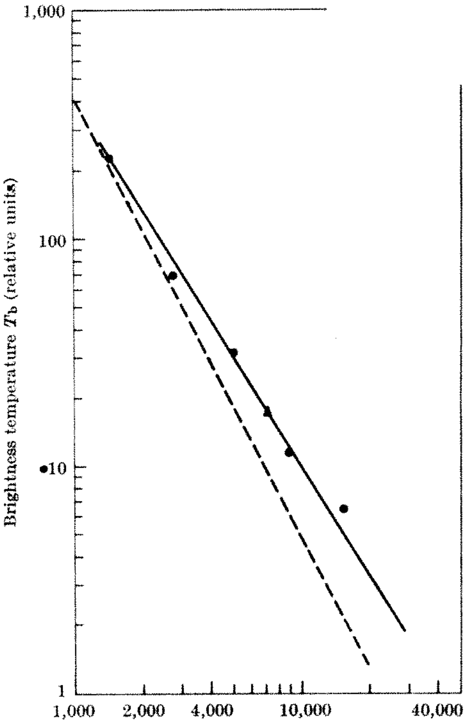

Fig. 4. Brightness temperature for the corona at centimetre wavelengths. The dashed line represents similar data for the eclipse of November 12, 1966.

The eclipse at Sagamore Hill was almost total. Hence it was possible to consider the residual flux at maximum phase as coming from beyond the solar disk. Using an approach similar to that applied by Kaufmann and Matsuura for the eclipse of November 12, 1966 (ref. 6), a plot of relative brightness temperature versus frequency for the residual was obtained. By this method the spectral index of the Sun at centimetre wavelengths can be approximated for different periods of the sunspot cycle. An attempt was made to normalize the values of the data for March 7, 1970, so that the two eclipses could be compared. The resulting plot is shown in Fig. 4, where the dashed curve is that given in Fig. 1 of ref. 6. The data from the 1970 eclipse have a flatter spectrum with a spectral index γ of $-1{\cdot}5$ ($T_b = af^\gamma$), compared with the index of $-1{\cdot}9$ for the 1966 eclipse. It is interesting that Tanaka and Kakinuma show that when the spectra of monthly mean values of the total solar flux are plotted as a function of period within the solar cycle, the spectra indeed flatten out during periods of high solar activity (paper at the Fifteenth General Assembly of URSI, Munich, 1966). For the mid-centimetre wavelengths, the Sun was considerably hotter on March 7, 1970, than on November 12, 1966.

Although the results are preliminary, it is apparent that the single source analysed, with its spectral peak near 6 cm, must be considered a representative source of the slowly varying component. It is possible that typical slowly varying sources are not important for burst production, but this requires further investigation. The non-radial distribution of the source under investigation seems real and confirms findings from at least one earlier eclipse[3].

We thank Drs O. Matsuura and P. Kaufmann for

16 GHz Observations of the Eclipse

THIS letter presents the preliminary results of eclipse observations at a frequency of 16 GHz (1·9 cm) on March 7, 1970. The data define the diameter of the radio Sun at the 16 GHz observing frequency, and the initial analysis indicates non-uniform emission from both the limb and disk regions. The transportable radio telescope (Fig. 1) was located at Virginia Beach, Virginia (lat. 36° 50′ 19″ N, long. 76° 01′ 25″ W). It consists of a steel flatbed trailer which is raised on mechanical jacks when on site. A precision elevation over azimuth pedestal is employed. After rough levelling with the jacks, a rotating table and adjustable tilt base allow the pedestal to move in right ascension and declination. The offset paraboloid antenna, of aperture 40 inches, has a 1·5° beamwidth at 16 GHz. The first sidelobe levels are more than 30 dB below the main lobe gain. Two multimode feed horns are equally displaced in a horizontal plane by one half the horn diameter about the prime focus of the antenna. One beam is directed at the Sun and the other is $-3·5°$ from the Sun in right ascension. The receiver alternately samples the two signals at a rate of 1 kHz. The result of this two-beam technique is the subtraction of the atmospheric emission background, leaving only the signal due to the Sun.

The superheterodyne receiver has a mixer using a balanced Schottky barrier diode designed by W. M. Sharpless. The noise temperature is 1,200 K and the double sideband 3 dB bandwidth is 450 MHz. The signal was synchronously detected during the eclipse using a 12 s time constant and recorded on strip chart recorders. The output was linear within 2 per cent over a -20 dB range from the normal solar signal, with a signal resolution of approximately 1 part in 10^4. The observed fluctuations on the signal were due entirely to receiver gain variations and were approximately proportional to the signal level. The signal to noise ratio was approximately 75.

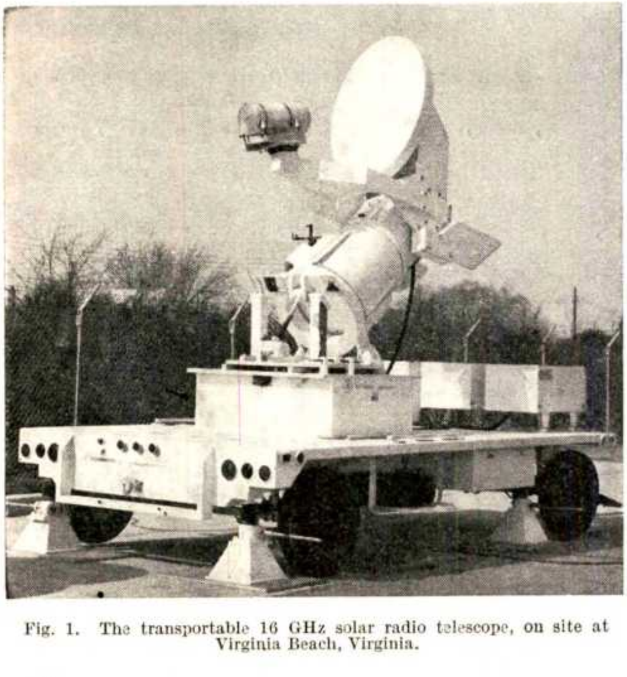

Fig. 1. The transportable 16 GHz solar radio telescope, on site at Virginia Beach, Virginia.

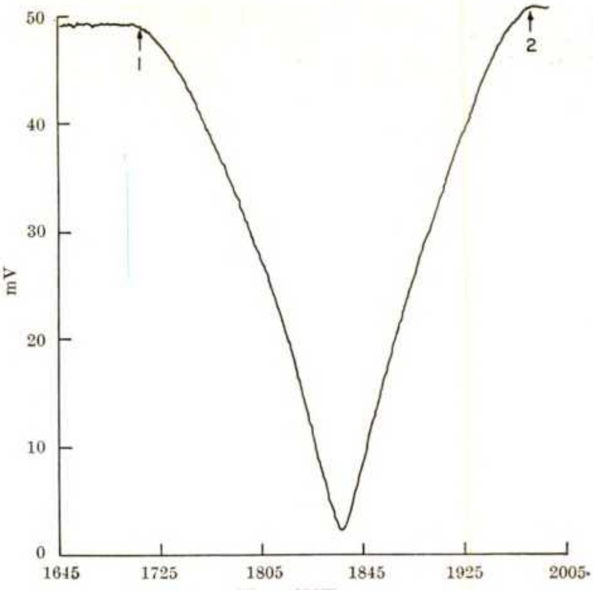

Fig. 2. The March 7, 1970, solar eclipse, as observed at 16 GHz. This figure is a computer representation of the original data and does not represent the inherent resolution of the experiment. Voltage values are linearly convertible to temperature, but the necessary parameter has not yet been derived. Points 1 and 2 indicate the beginning and end of the radio eclipse, as determined from the unsmoothed data.

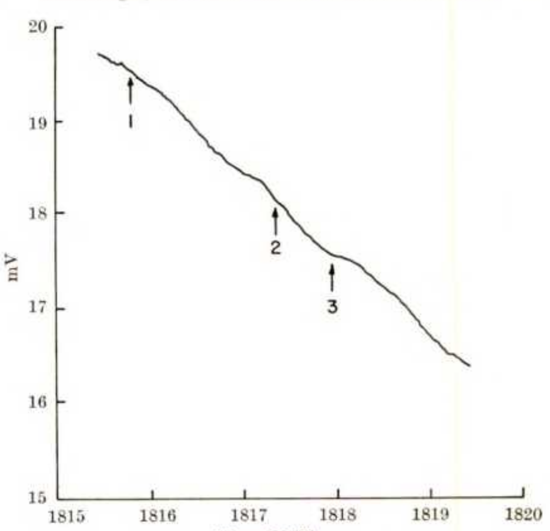

Fig. 3. The occultation of a large sunspot group by the Moon during the March 7, 1970, eclipse. Point 1 indicates the time at which occultation of a sunspot was optically observed to begin. Point 2 indicates the time at which occultation of a second sunspot began. The completion of the optical occultation is indicated by point 3. (See caption to Fig. 2 for comment on ordinate scale.)

The basic eclipse data at 16 GHz are shown in Fig. 2 and the points of first and fourth contact for the radio data are also indicated. The first and fourth radio contact occurred approximately 90 ± 10 and 85 ± 10 s before and after the respective optical contacts. This implies an average 16 GHz radio diameter for the Sun of $1·038 \pm 0·002$ times the optical diameter. The maximum of the radio eclipse occurred 18 ± 4 s after the optical maximum, implying an asymmetry of the radio Sun as a result of extended emission from regions on the NE limb. The larger values observed for the time derivative of the signal strength following the maximum radio eclipse as compared with pre-maximum values, along with the relatively early time of first radio contact, suggest that McMath plage region 10621, on the SW limb, was a small but bright source of emission at 16 GHz. The residual signal at maximum eclipse is 2·6 ± 0·2 per cent of the uneclipsed solar value, which implies a solar radio diameter of 1·039 times the optical diameter.

A detailed study of the data for the purpose of reconstructing the structural features of the radio disk has not yet been completed, but some preliminary results are available. Upon occultation of the large sunspot group at S15E40 (McMath plage region 10618), a decrease in the magnitude of the slope was observed, indicating the presence of a cool region on the disk. This is illustrated in Fig. 3. The occultation of the sunspot at W38N07 (McMath plage region 10607) has also been seen on the 16 GHz data.

Our preliminary results are summarized as follows: (1) The solar radio diameter at 16 GHz (1·9 cm) was 1·038 ± 0·002 times the solar optical diameter. This result is larger than that determined from a previous eclipse observation[1] by Shih-weh *et al.* at 18·8 GHz (1·6 cm) and approximately equal to previous determinations[1,2] at 10 GHz (3 cm), and may be indicative of the relatively high level of solar activity present during this eclipse. (2) The residual flux at maximum eclipse was 2·6 ± 0·2 per cent, in reasonable agreement with values derived from previous observations[3]. (3) Effects of sunspots and other non-uniformities were seen in the data. Detailed analysis of the structural features of the radio Sun is continuing.

Observations with a 7 GHz Polarimeter

THE eclipse of March 7, 1970, was observed at 7 GHz with a polarization solar radio telescope at Sagamore Hill Radio Observatory (AFCRL), Hamilton, Massachusetts, where the magnitude of the eclipse was 0·96. We used basically the same equipment for the eclipse of November 12, 1966 (refs. 1–3). Two outputs were available, one proportional to the total solar flux ($S_R + S_L$), and the other to the difference in flux between the right and left-handed components of circular polarization ($S_R - S_L$). The degree of polarization is then the ratio of the outputs $(S_R - S_L)/(S_R + S_L)$. Solar activity was monitored before and after the eclipse date.

Fig. 1 shows the eclipse curve obtained after preliminary reduction of the data, where the time resolution was better than 20 s. Fig. 1 also shows the standard deviation of averaged values of the degree of polarization for each interval of 2 min.

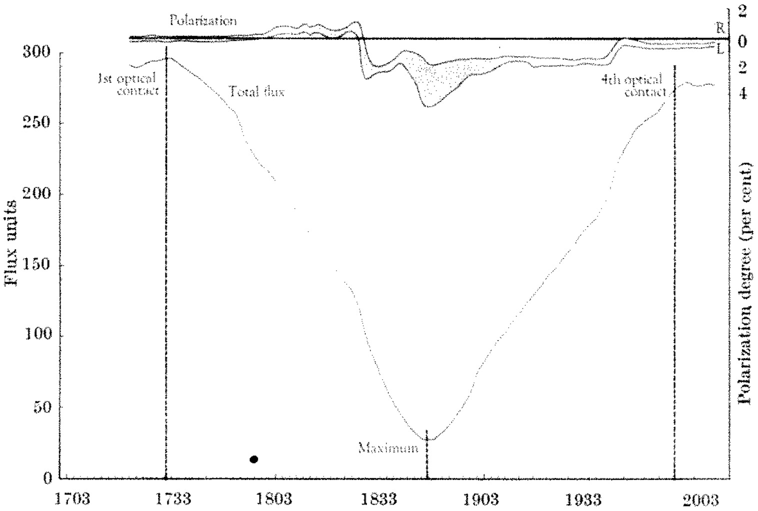

Fig. 1. The eclipse curve at 7 GHz, taken at intervals of 2 min. The upper curve refers to the total degree of circular polarization and represents the limits of the r.m.s. variations in intervals of 2 min.

Shortly before the eclipse maximum at ~18·45 UT, only the northern hemisphere of the Sun was visible, and the polarization was definitively left-handed. This result supports the possible emission of polarized radio waves from the northern solar hemispheres[3], but this is not certain because important coronal condensations which could influence the polarization effect were reported by optical observers.

Fig. 2 is the derivative of the eclipse curve[4], taken in intervals of 2 min of time, which indicates the presence of stronger active regions. At least two extended regions can be identified, one with intensity greater than 10 flux units and the other greater than 40 f.u. Most of the active regions were not strongly polarized, excepting region No. 2 (probably associated with McMath plage 10618 in the solar eastern hemisphere) which contributed 48 f.u. During the eclipse of this large active zone, a smaller region with strong right-handed polarization was covered and computations showed that its degree of polarization was about 10 per cent. It could have been the preceding part of a relatively complex sunspot group.

Burst activity at metric wavelengths was reported by AFCRL, Sagamore Hill, at about 1830 UT, close to the maximum of the eclipse. The activity did not appear at frequencies greater than 606 MHz, but it is possible that the S-component where such bursts originate did not remain stable during the eclipse, explaining some of the asymmetries in the eclipse derivative curve.

The residual flux at the maximum of the eclipse was nearly 8 per cent of the total solar flux and nearly 13 per cent of the quiet solar flux (deduced from the derivative curve and corrected for the contribution from the Moon), a figure larger than that obtained during the

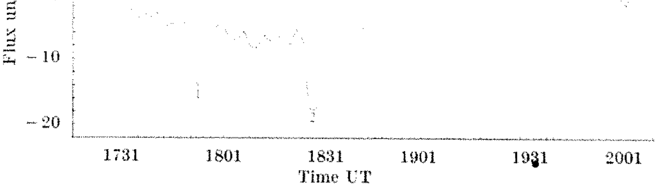

Fig. 2. The eclipse derivative curve, based on time intervals of 2 min.

1966 eclipse[2,5], because this time part of the solar disk was still visible.

The diameter of the radio sphere was not determined with great accuracy. Just before first contact the burst activity reported at 200 MHz could have influenced to some extent the activity at 7 GHz. From the more definite fourth contact and the eclipse derivative curve we expect the existence of detectable coronal emission at 7 GHz for heights lower than 1·2 solar radii.

Radio Observations of the Distribution of Chromospheric Brightness Temperature

MODELS of the temperature and density distributions in the solar chromosphere may be tested by radio observations of the dependence of the brightness temperature on wavelength and position across the solar disk. The general increase in brightness temperature T_b at the centre of the disk with increasing wavelength of observation λ is well described[1] by the van de Hulst model[2] and also by the BCA model[3]. If such models are taken to be spherically symmetric, then the distribution of brightness temperature across the solar disk at a given wavelength is expected to increase toward the limb as sec θ, where sec $\theta = (1-\rho^2)^{-1/2}$, ρ being the position, in units of the solar radius, on the disk. The amplitude of the sec θ variation is determined by the dependence of the optical depth on height. Thus, although the $T_b - \lambda$ and $T_b - \rho$ distributions are interrelated, the $T_b - \rho$ distribution may be interpreted as an indication of the geometrical structure of the chromosphere in the sense that its functional form depends on the geometry. The earliest evidence of failure of the sec θ distribution, and hence failure of the assumption of spherical symmetry, came from the eclipse observations of Coates, Gibson, and Hagen[4] at 8·6 mm which revealed a flat distribution across the disk and a possible spike at the limb. More recently, high resolution observations (resolutions less than 3 min of arc) of the quiet Sun have revealed similarly flat distributions to $\rho \sim 0{\cdot}8$ over the range 3·5 mm to 2 cm (ref. 5). These observations and the recent observations in the ultraviolet have been interpreted by Simon and Zirin[6] in terms of a rough structure of the solar chromosphere (similar in spirit to the spicule interpretation of the 8·6 mm limb spike by Coates[7] and Athay[8]). Provided that the scale of roughness is small compared with the observational resolution, the rough surface would present the same mean brightness temperature at all but the most extreme aspect angles. Thus a narrow region of limb brightening close to the limb is to be expected. The high resolutions necessary to resolve structure near the limb can be attained during an eclipse, and a cooperative effort was organized among those observatories near the eclipse path which can observe at cm and mm wavelengths. The observatories taking part in the March eclipse were: the University of Texas at Austin (2·1 mm, Cogdell), NRAO at Kitt Peak (3·5 mm, Simon), Aerospace Corporation (3·4 mm, Shimabukuro), Haystack facility of MIT Lincoln Labs (1·35 cm, Zapata) and NRAO at Green Bank (2 cm, Buhl). Poor weather in western Texas prevented observations there, but good data were obtained at the other observatories. The data that we have analysed most completely so far are at 3·4 mm and 1·35 cm, and we shall restrict our discussion to those. (A similar effort was carried out during the annular eclipse of September 11, 1969, and data over the range 2·1 mm to 3 cm were obtained.)

The general technique was to position the axis of the main beam of the antenna on the first and last contact positions on the lunar limb and to track those positions as they crossed the limb of the Sun. In effect, the antenna beam was thus "sharpened" by the knife edge of the Moon. In between the times of first and last contact high resolution observations of other regions on the Sun were possible (within the obvious limitations of the local eclipse geometry) by tracking the appropriate position on the lunar limb.

The 3·4 mm data obtained at first contact are shown in Fig. 1. The data points were taken every 6 s with a time constant of 1 s (at times later than ~1633 UT we have displayed only every other data point). The data were corrected for atmospheric extinction and normalized to unity by averaging over the time interval from around 1650 to 1700 UT (during which the antenna was passing over $\rho \sim 0{\cdot}7$ on the solar disk). The short term scatter of the points is consistent with the 2–3″ tracking "jitter" of the antenna. The line through the data is an "eye" fit. At 1·35 cm the data were taken every second with a one second time constant. The 1·35 cm points in Fig. 2 for the last contact are 10 s averages, and the data were normalized to unity over the time interval from around 1932 to 1940 UT when the antenna was passing over $\rho \sim 0{\cdot}3$ to $\rho \sim 0{\cdot}5$. The scatter in these points is also consistent with the monitored antenna tracking errors and the line drawn through them is again an eye fit to the data.

Both these records yield information much nearer to the solar limb than has been available previously. For example, in Fig. 1, the antenna was at $\rho \sim 0{\cdot}97$ on the solar disk at 1630 UT and in Fig. 2 was at $\rho \sim 0{\cdot}95$ at 1955 UT. Inspection of Hα photographs of the Sun for March 7 reveals that in the regions covered by the scans represented in Figs. 1 and 2 there were no obvious active regions so that the scans are presumably representative of the quiet Sun. (There were, however, active regions close to the point of last contact at 3·4 mm and to the point of first contact at 1·35 cm which appear as brightness enhancements on those scans.)

The general roughness of the brightness temperature distribution is evident in both figures. The amplitude of

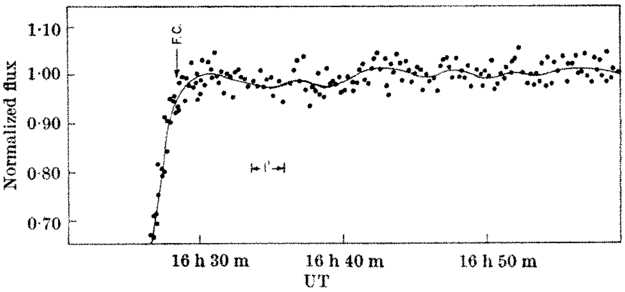

Fig. 1. First contact data obtained at 3·4 mm with the 15-foot telescope of the Aerospace Corporation. The time of first contact (F.C.) and one min of arc scale size on the Sun are indicated.

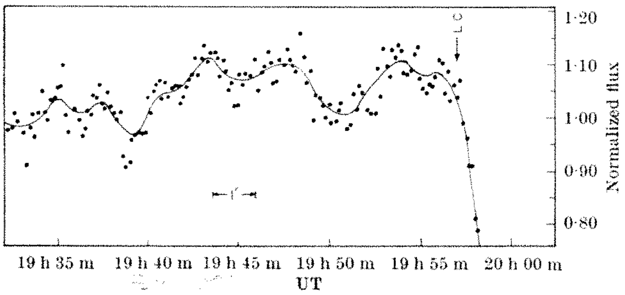

Fig. 2. Last contact data obtained at 1·35 cm with the 120-foot Haystack telescope of MIT–Lincoln Laboratory. The time of last contact (L.C.) and one min of arc size are indicated.

the fluctuations is much greater at 1·35 cm than at 3·4 mm, and in both cases the smallest half-width of the smoothed fluctuations of brightness temperature is about half a minute of arc. (The intrinsic, or "non-eclipse", half-power beam width of the Aerospace Corporation telescope used to obtain the 3·4 mm data was 2·8′, and 1·4′ for the Haystack antenna at 1·35 cm.) In our analysis of the 3·4 mm data from the eclipse of September 11, 1969, and also from the 3·5 mm data for this eclipse, we found that some of the brightness temperature dips correlate well with positions of filaments observed in Hα. This is not the case here, as there were no filaments near the scan tracks represented in Figs. 1 and 2. The general character of the 3·4 mm distribution in Fig. 1 is consistent with the extensive solar mappings at 3·5 mm carried out by Buhl and Tlamicha[9] with 1·2′ resolution. In those observations the distribution of brightness temperature for the quiet Sun appeared to have fluctuations on the scale of the instrumental resolution, and also there were indications that filaments were beginning to be resolved. It is interesting to note that the size scale of the fluctuations resolved in Figs. 1 and 2 is comparable to the typical size of the chromospheric network, and we may speculate that in fact the fluctuations are determined by the chromospheric network.

Allowing for the generally undulating nature of the 3·4 mm distribution in Fig. 1, it is seen that there is little, if any, direct observational evidence of limb brightening. By convolution of various models of limb brightening, we can place an upper limit of 1 per cent on the total power that might be contained in an annulus of limb brightening at the limb, and an upper limit of 0·03 $R_{\odot}$ on its width. These results are consistent with analysis of the 3·4 mm observations during the September eclipse.

There is clear evidence of limb brightening in the 1·35 cm observations from the generally enhanced brightness temperature at the time of last contact (compare also the rate of drop-off of the brightness temperature at the time of contact in the two figures). The enhancement prior to 1950 UT (when the antenna was at $\rho \sim 0{\cdot}8$) should not be considered to be limb brightening because Tlamicha's observations[5] showed that the distribution of the undisturbed Sun is statistically flat to at least $\rho \sim 0{\cdot}8$. Rather, we believe that the fluctuations observed at $\rho < 0{\cdot}8$ should be interpreted as contributing, when at the limb and foreshortened, to the enhancement observed at the limb.

The preliminary analysis of the data that we have carried out so far therefore indicates that fluctuations of brightness temperature of about 0·5 minute of arc in size on the undisturbed Sun have been resolved, and that their amplitude increases with the wavelength of observation. Their size suggests an origin in the chromospheric network.

We thank the many individuals who contributed to these observations. We also thank R. L. Duncombe of the US Naval Observatory for calculations of the local circumstances and J. V. Lincoln of World Data Center A, Environmental Science Services Administration, for optical data. Effects on Migration of Marine Organisms in the Gulf of Mexico

THE research vessel Alaminos from Texas A & M University was in the Gulf of Mexico on March 7 to record changes in the near-surface layers of sea and air as a consequence of the eclipse. So that a maximum variation in incident solar radiation could be realized, the observing site was chosen at 24° N and 89·5° W where totality would occur approximately at local solar noon over waters deeper than 100 fathoms.

Among the aims of the cruise were measurements of the vertical migration of zooplankton in the near-surface layer, the depth of the deep-scattering layer, and indications of biological productivity.

A preliminary examination of acoustic reverberation records taken at 12 kHz revealed the existence of four or five deep scattering layers—layers of concentrated marine organisms—during the 3 days on the day before, during and after the eclipse. These were at depths of 20–250 fathoms. During the test period the layers showed the characteristic upward migration around sunset and downward migration at sunrise.

Several of these layers seem to have responded to the eclipse but only one displayed a definite and measurable reaction (Figs. 1*d* and 2*d*). This layer, at 80 fathoms on each day during the test period, migrated upward about 4 fathoms, but the migration lagged behind the eclipse by about 20 min. The layer also responded to several periods of relatively heavy cloud on the afternoon of the day of the eclipse and the following day. The evening upward migration seems to have started earlier (about 1500 h) on the day of the eclipse than on the day after (about 1730 h). This may have arisen from confusion in the layer, or a rougher sea on the following day, so that more light entered the sea in the later afternoon.

The near-surface zooplankton population was sampled by periodic 10 min tows at a standard wire angle with an array of 12 inch Clarke–Bumpus plankton samplers. Concurrent sampling at four depths from the surface to 75 m below was customary, although only surface and 25 m samples were obtained during totality.

An impression of the relative volume of plankton samples taken at these two depths during the 1·5 days of observation can be obtained from an examination of the settled material (Figs. 1*b*, *c* and 2*b*, *c*). We are reluctant to speculate on the significance of the data, but there does seem to have been a relative increase in the volume of zooplankton near the surface and a decrease at 25 m during the darkest moments of the eclipse. A similar increase is evident for the following evening and may represent upward migration of certain elements of the zooplankton community in response to decreased levels of light intensity. We note, however, that this does not seem to have been the case at these depths during the night before the eclipse.

Initial examinations of the samples reveal a predominance of copepods, euphausiaceans, chaetognaths and small decapods. But because observations of the vertical migration of marine zooplankters can be considered valid only in relation to individual species, meaningful conclusions must await further analysis.

During this cruise the standing crop of phytoplankton was estimated by determining the chlorophyll *a* content spectrophotometrically (using a D-U spectrophotometer) and fluorometrically (using a Turner fluorometer, model 111) during the period March 6–8, 1970. Continuous fluorometric monitoring of chlorophyll *a* in near-surface seawater (depth, 3 m) did not show discernible variations in the standing crop of phytoplankton at comparable times during the observations. Integrated chlorophyll *a* values of water samples collected in the water column from the surface down to 50 m at 1045 h on March 6, 7 and 8 were 17·72, 11·76 and 11·82 mg/m², respectively. Unfortunately, the data collected on phytoplankton are not sufficient to suggest a cause and effect relationship; other factors, grazing, for instance, could be implicated in explaining the decrease in the phytoplankton biomass during and following the solar eclipse day.

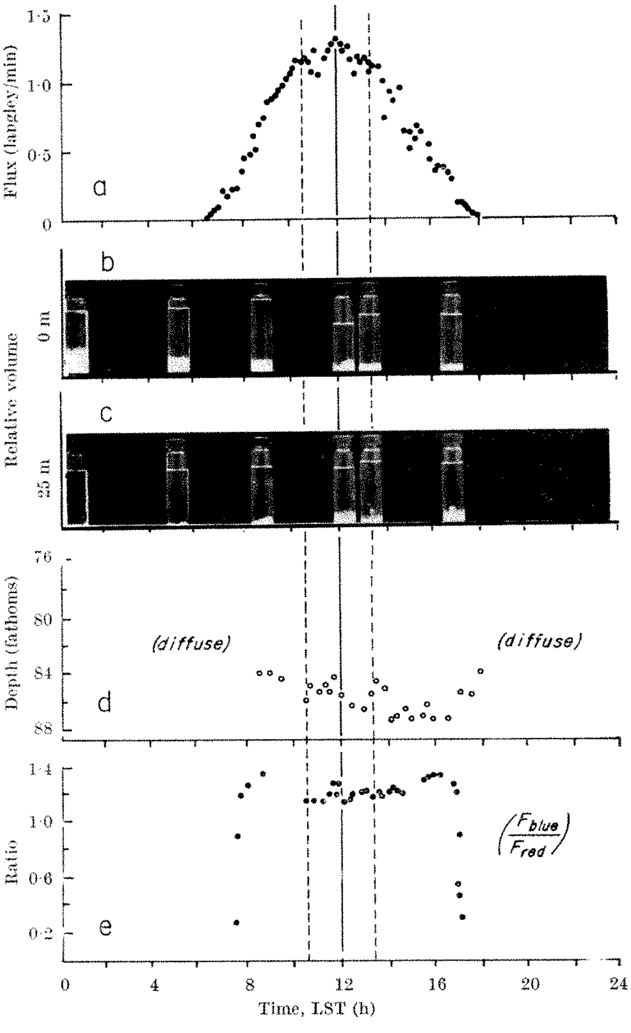

Fig. 1. Diurnal variations on March 8, 1970, of insolation, measured with a pyranometer which incorporated a silicon photovoltaic cell as sensor, mounted on the weatherdeck (*a*); relative volume of zooplankton near surface (*b*) or at 25 m (*c*); depth of a deep-scattering layer (*d*); and (*e*) ratio of blue to red solar radiation.

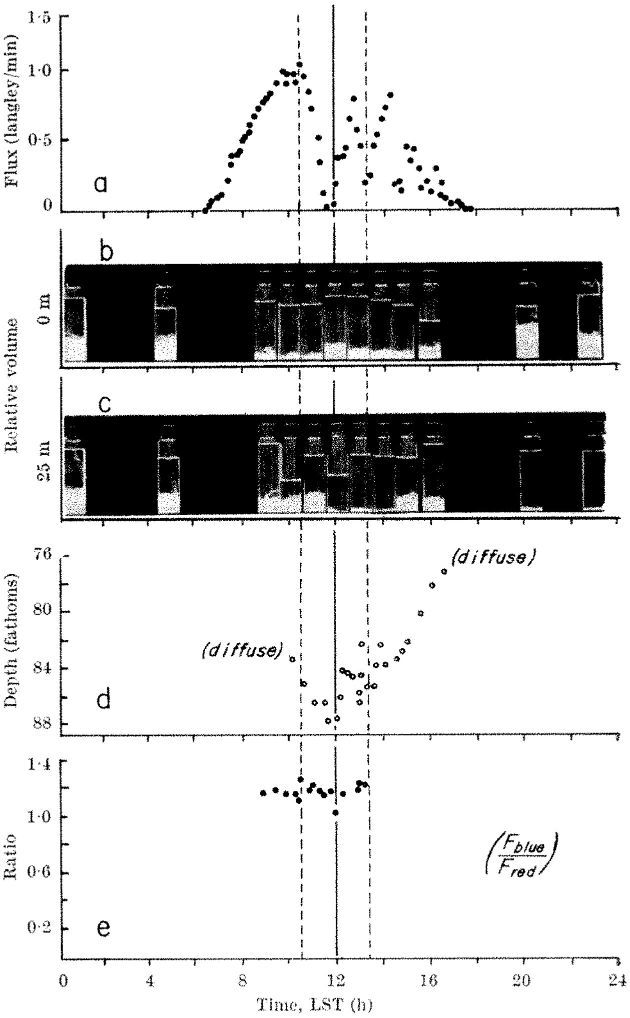

Fig. 2. Same as Fig. 1, but for the day of the eclipse, March 7. The sky was cloudy from 1530 to 1640 LST. When the solar disk was half covered, near 1127 LST, insolation was reduced to 40 per cent of the unobscured value for the same time on the following day. Presumably thin strato-cumulus clouds accounted for the additional 10 per cent reduction.

Hormones in the Translational Control of Early Germination in Wheat Embryos

by
DAVID CHEN*
DAPHNE J. OSBORNE
**ARC Unit of Experimental Agronomy,
Department of Agricultural Science,
University of Oxford**

Gibberellic and abscisic acid seem to exert their effects on germination by acting in some way at the level of translation. The two hormones may act at different sites.

THERE is at present much interest in two ways in which hormones may regulate the rate and pattern of growth and differentiation—the transcription of informational RNA from the DNA template[1] and the translation of informational RNA in processes of protein synthesis[2]. Both mechanisms may be operative in plant systems[3,4], but the continued transcription of RNA from DNA by most growing tissues makes precise interpretation of the data difficult. In germinating wheat embryos, however, the genome is essentially inactive for the first 12 h and no mRNA is transcribed[5]. Nevertheless, protein synthesis is initiated within 30 min of the embryos imbibing water, indicating that a functional informational and translational system is present within the tissue[6,7].

We have used wheat embryos to study the effects of two plant hormones, gibberellin A3 (GA) and abscisic acid (ABA), on the processes of protein synthesis. Both hormones regulate the growth of the embryos, GA as an accelerator of germination, and ABA as an inhibitor.

The effects of a range of concentrations of GA and ABA on the germination of wheat embryos were determined using the procedures described in Fig. 1. When 10^{-4} M GA was present in the germination medium, development of the embryos was advanced; at 12 h root emergence could already be detected and by 24 h fresh weight was 20 per cent higher than that of controls. Although barley embryos are considered to be a source of GA[8] which includes the *de novo* synthesis of certain enzymes in the aleurone of the endosperm[9–11], it is evident that added gibberellin also enhances the growth of the embryo[12]. When 10^{-4} M ABA was included both in the agar medium and in the germination medium, germination was inhibited, and the fresh weight was 28 per cent less than the controls.

DNA Synthesis

Both GA[13] and ABA[14] are reported to affect DNA synthesis, but it is not clear whether the hormones control the actual initiation of DNA replication. This was checked in wheat embryos by following the effects of the hormones on the incorporation of radioactive precursors into DNA. After 7 and 23 h germination in the presence of germination medium, or germination medium with GA, embryos were pulsed with ^{14}C-thymidine for 1 h before analysis. No radioactivity above background was found in the trichloroacetic acid (TCA) insoluble fractions labelled during 7–8 h of germination, nor in the isolated and purified DNA[7] (Fig. 1*a* and *b*). Moreover, during the period after which DNA replication is initiated (24 h), no stimulating effects of GA on the rate of DNA synthesis were observed. Clearly, the initiation of replication is not under direct control by GA. The results agree with those of Haber[15], who concludes that DNA synthesis is not a requirement for growth regulation by GA. By contrast, ABA depresses the rate of DNA synthesis once it has been initiated.

RNA Synthesis

If plant hormones function at the gene level[16] there must be induction or repression of specific gene products coding for the induced enzymes. Most evidence, however, indicates an overall stimulation of RNA synthesis in plants treated with hormones[17–20]. Because the synthesis of RNA in germinating wheat embryos is repressed during the first 12 h of germination[5], it should be possible in this system to detect an earlier RNA synthesis induced by hormones. Embryos germinated in GA and ABA were therefore pulsed with ^{3}H-uridine for 1 h between 11 and 12 h of germination. The values for ^{3}H-uridine incorporated, as percentage of total uptake, show that RNA synthesis is switched on only after 12 h of germination, irrespective of the presence of GA or ABA (Fig. 2). The level of these analyses does not preclude the possibility that a small and specific functional RNA is included in the early hours of germination. But clearly, by 24 h, the rate of total RNA synthesis is enhanced by 22 per cent in embryos treated with GA and reduced by 49 per cent by ABA.

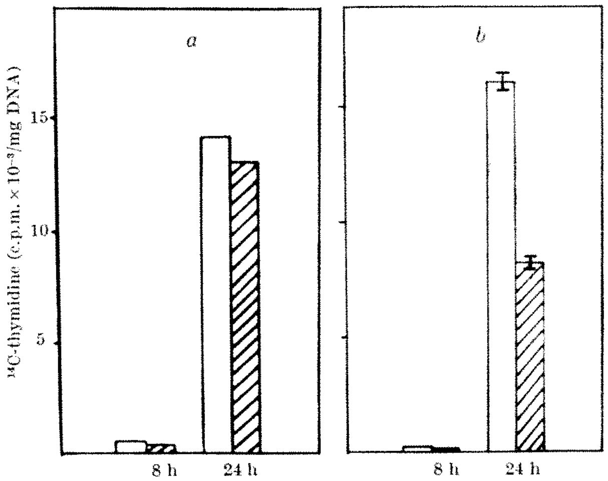

Fig. 1. Effects of GA and ABA on DNA synthesis. Wheat embryos were germinated in 3 cm sterilized Petri dishes on a 1 per cent agar medium containing 2 per cent sucrose and 10 µg/ml. chloramphenicol. Germination was started by adding to the embryos on the surface of the agar 0·6 ml. of 0·005 M *tris*-(hydroxymethyl)-aminomethane buffer (*p*H 7·6), 0·02 M KCl, 20 µg/ml. sucrose, 10 µg/ml. chloramphenicol (germinating medium, GM) or GM including either GA or ABA (1×10^{-4} M). The plates were then maintained in darkness at 25° C. After 7 and 23 h, they were transferred for 1 h to a corresponding medium containing 1 µCi/ml. ^{14}C-thymidine (Radiochemical Centre, Amersham; 56 mCi/mmole). Embryos were then homogenized in 5 ml. of 0·1 M EDTA–saline buffer (*p*H 8). DNA was isolated from the total homogenate, purified as previously described[7] and plated on to glass fibre filters ('GFA') and the radioactivity counted in a Beckman scintillation counter. Background values for the absorption of radioactivity were estimated in dry and germinated embryo samples homogenized in the presence of the radioactive precursor medium and processed as for the experimental samples. Open areas, controls. Hatched areas: *a*, 1×10^{-4} M GA; *b*, 1×10^{-4} M ABA.

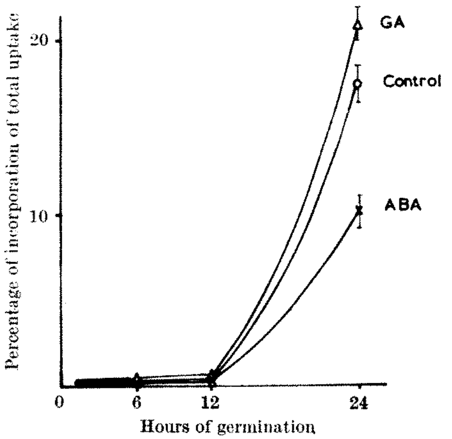

Fig. 2. Effect of GA and ABA on incorporation of uridine. Wheat embryos, 300 mg per sample, were germinated in the presence of GM or GM containing 1×10^{-4} M GA or ABA as described in Fig. 1. After 11 h the embryos were transferred to the respective radioactive media containing 15 μCi/ml. ^{3}H-uridine (Radiochemical Centre, Amersham; 19·2 Ci/mmole) for 1 h before analysis. The embryos were then homogenized in 5 ml. of 0·01 M Tris (*p*H 7·8), 0·02 M KCl, 0·01 M $MgCl_2$ (TM buffer) and 1 ml. aliquots were diluted with 5 ml. of 5 per cent TCA, filtered on 'GFA' glass fibre filters, washed sequentially with 10 ml. 5 per cent TCA, 3 ml. of ethanol, 3 ml. ether; then dried and counted. Aliquots (0·1 ml.) of the original homogenate were dried on 'GFA' filter discs and the radioactivity was counted for the estimation of total uptake of ^{3}H-uridine. Absorption backgrounds were estimated as in the legend to Fig. 1.

Protein Synthesis

Protein synthesis is initiated in the germinating wheat embryo immediately after imbibition[6] and evidence suggests that this early protein synthesis is programmed by a masked mRNA preserved in the dry embryo[5,7]. We now report the effects of GA and ABA on protein synthesis during the first 24 h of germination. Embryos were germinated in GA or ABA and pulsed with a ^{14}C-amino-acid mixture for 30 min before analysis. A stimulation of amino-acid incorporation by GA can be detected as early as 8 h, and by 24 h incorporation is 20–30 per cent higher than that in the controls (Fig. 3). With ABA, however, there was no detectable difference between treatments and controls for the first 6 h, but subsequently incorporation was inhibited by ABA (Fig. 4).

If the rate of protein synthesis in GA and ABA were a reflexion of the extent of polysome formation, this should be detectable in the distribution pattern of the isolated ribosomes. Ribosomes were therefore isolated[7] from embryos that were germinated for 12 h in germination medium alone, or in germination medium containing GA or ABA. They were layered on a sucrose gradient which was centrifuged and fractionated. The spectrophotometric analysis showed that the resulting absorbance patterns did not differ between the various treatments (Fig. 5*a*).

When ribosomes isolated from control 12 h embryos were incubated with either GA or ABA for 10 min at 20° C no differences were found in the subsequent distribution pattern of the ribosomal population, an effect reported before for ABA in leaf tissue[20]. But when embryos were pulsed with a ^{14}C-amino-acid mixture between 11 and 12 h of germination, the ribosomes fractionated from GA treatments—although exhibiting no difference in absorbance pattern compared with controls—displayed enhanced incorporation over the whole gradient. By contrast the ribosomes isolated from ABA treated embryos manifested reduced levels of amino-acid incorporation (Fig. 5*b*) compared with controls.

In other experiments, ribosomes isolated from 12 h embryos pretreated with GA or ABA were purified and tested for their endogenous mRNA activity in a cell free amino-acid incorporating system, saturated with tRNA and supernatant obtained from wheat germ. The results (Fig. 6) show that ribosomes from GA treated embryos display a 23–28 per cent higher template activity than controls, but ribosomes from ABA treated embryos have a slightly decreased activity (15–20 per cent) with respect to the equivalent amount of control ribosomes.

We have also tested whether the ribosomes *per se* are altered by the addition of the hormones *in vivo*. Stripped ribosomes from GA and ABA treated embryos were incubated in the standard cell free system together with poly U and ^{14}C-phenylalanine. Neither GA nor ABA treatment affected the capacity of the ribosomes to support peptide bond formation. The values for ^{14}C-phenylalanine incorporated by the three different ribosomal preparations in a typical experiment were 288,820, 276,100 and 275,610 c.p.m. per mg ribosomes.

The effect of a direct addition of GA or ABA to the cell free system primed by poly U has also been determined (legend to Fig. 6). ABA has a direct inhibitory effect on incorporation ranging from 10 per cent at $1·25 \times 10^{-5}$ M to 30 per cent at $2·5 \times 10^{-4}$ M. Similar effects are found with GA; however, at 10^{-5} M, inhibition was approximately 5 per cent and rose to 24 per cent at 2×10^{-4} M. This experiment rules out the possibility of a direct stimulating

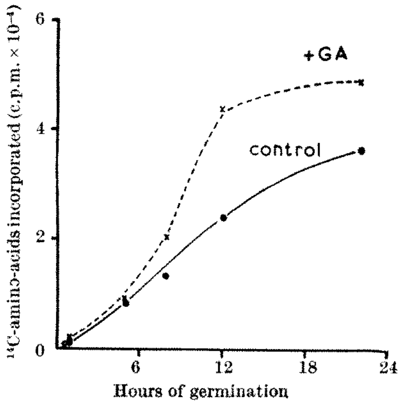

Fig. 3. Effects of GA on incorporation of amino-acids. Wheat embryos, 300 mg per sample, were germinated for different times before being transferred for 30 min into GM solutions containing 1 μCi/ml. ^{14}C-amino-acid mixture (New England Nuclear, 1·2 mCi/mg) with or without 1×10^{-4} M GA. The embryos were then washed with 30 ml. of GM containing 0·5 mg/ml. protein hydrolysate, homogenized in 8 ml. cold 5 per cent TCA, heated for 15 min at 90° C, and cooled; 0·5 ml. aliquots were filtered on sartorius membrane filters (0·45 μm), dried and the radioactivity was counted. Results are expressed as total counts incorporated into the embryo sample, but the pattern is similar if expressed as per cent incorporation of total uptake. Absorption backgrounds were estimated as in the legend to Fig. 1.

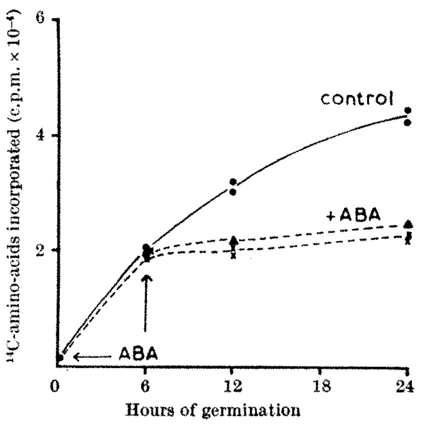

Fig. 4. Effect of ABA on protein synthesis. Wheat embryos, 300 mg per sample, were germinated in GM (●—●), or GM containing 2×10^{-4} M ABA (×---×). In one set of samples, embryos were germinated for 6 h in GM before being transferred to GM + ABA medium (▲---▲). At various intervals the embryos were transferred for 30 min to the respective medium containing 1 μCi/ml. ^{14}C-amino-acid mixture and processed; the radioactivity was counted, and the results are expressed as in the legend to Fig. 3.

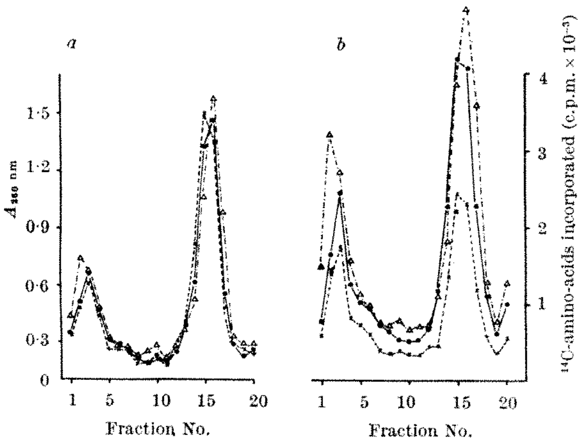

Fig. 5. *In vivo* effects of GA and ABA on distribution pattern (*a*) and activity (*b*) of ribosomes. Wheat embryos, 500 mg samples, were imbibed in GM or GM containing 1×10^{-4} M GA or ABA. After 11 h the germinating media contained 2 µCi/ml. ^{14}C-amino-acid mixture (New England Nuclear, 1·2 µCi/µg). Ribosomes were isolated from embryos after 12 h of germination by homogenizing them in 10 ml. of 0·05 M Tris (*p*H 7·8), 0·01 M $MgCl_2$, 0·025 M KCl, 0·5 M sucrose–0·005 M mercaptoethanol (R buffer) and centrifuging for 20 min at 12,000 r.p.m. The supernatant was then centrifuged for 2 h at 50,000 r.p.m. in the Spinco '65' rotor, the pellet dispersed in 10 ml. of R buffer and recentrifuged for 45 min at 50,000 r.p.m. The pellet containing the ribosomes was dispersed in 1 ml. of TM buffer, centrifuged for 10 min at 10,000 r.p.m., and 0·3 ml. aliquots were fractionated on 5–20 per cent sucrose gradient (Spinco 'SW 39' rotor, 36,000 r.p.m., 45 min). Gradient fractions were analysed spectrophotometrically at 260 nm, precipitated by 3 ml. cold 5 per cent TCA, heated for 15 min at 90° C, cooled, filtered on to sartorius membrane filters, washed, dried and counted. ●—●, Control; △—·—△, GA; ×---×, ABA.

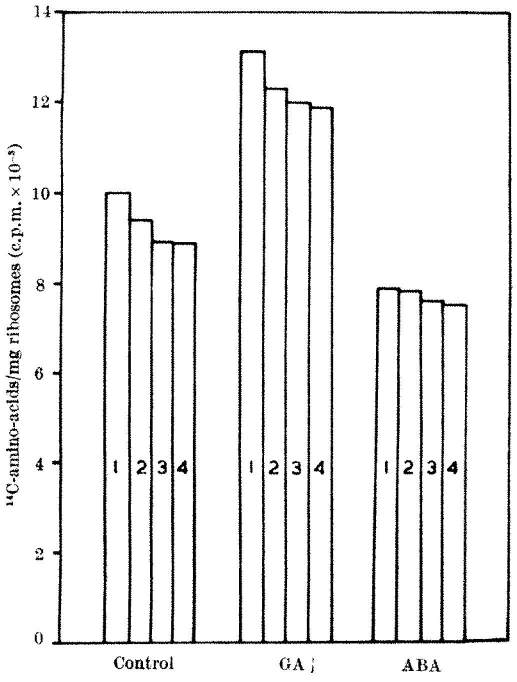

Fig. 6. Template activity of ribosomes from GA and ABA treated embryos. Wheat embryos, 1 g per sample, were germinated for 12 h in the presence of 1×10^{-4} M GA or ABA or GM only. Ribosomes were then isolated as described in Fig. 5 and the endogenous messenger activity was tested in a standard cell free system, containing (in a volume of 0·4 ml.) 22 mM Tris buffer (*p*H 7·8), 2·2 mM $MgCl_2$, 0·3 mM GTP, 0·4 mM ATP, 16 µg pyruvate kinase, 45 µg phosphoenolpyruvic acid, 6 mM mercaptoethanol, 50 µg tRNA (wheat), wheat germ 100,000*g* supernatant (0·5 mg protein), 100 µg ribosomes and 0·5 µCi ^{14}C-amino-acids (New England Nuclear, 1·2 mCi/mg). Incubation was at 25° C. The reaction was linear for 45 min but after 30 min the reaction was stopped with 3 ml. cold 5 per cent TCA. The precipitate was boiled for 15 min, cooled, filtered and counted. Background counts determined by adding ribosomes to the complete mixture were 200–300 c.p.m.

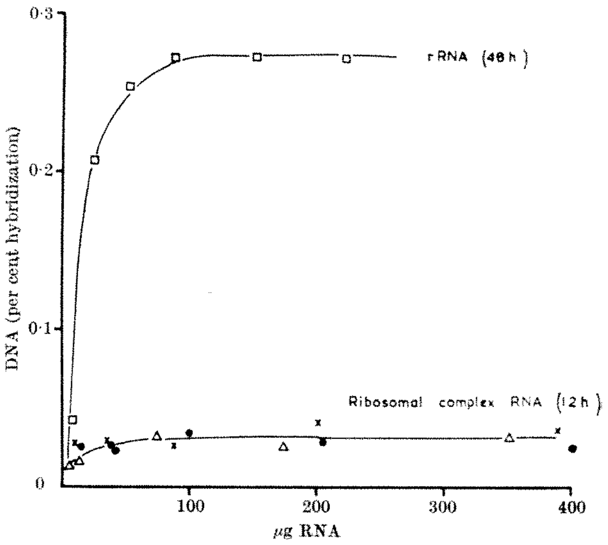

Fig. 7. Hybridization of DNA from 24 h germinated embryos with ^{3}H-RNA from the ribosomal complex. Embryos were germinated for 12 h in the presence of GA or ABA in media including 100 µCi/ml. ^{3}H-uridine. Ribosomes were isolated and their total RNA was extracted and extensively purified by two successive treatments with deoxyribonuclease followed by column chromatography on methylated albumin-kieselguhr, denaturation at 90° C for 3 min and filtration through nitrocellulose membrane filters. Increasing amounts of the RNA were annealed[5,22] with constant amounts of wheat embryo DNA (71 µg per filter). Purified rRNA was annealed as a control. The specificity of hybridization has been described[7]. ●, ^{3}H-RNA (519 c.p.m./µg) obtained from embryos germinated in GM; △, ^{3}H-RNA (620 c.p.m./µg) obtained from embryos germinated in GM containing 1×10^{-4} M GA; ×, ^{3}H-RNA (416 c.p.m./µg) obtained from embryos germinated in GM containing 2×10^{-4} M ABA; □, ^{32}P-rRNA (3,200 c.p.m./µg) from 48 h germinated embryos.

effect of GA on any of the transfer enzymes[21], but no conclusion can be drawn with regard to an effect on chain initiation or aminoacyl-tRNA synthetases (except for phenylalanine tRNA synthetase itself).

Enhanced activity of ribosomes from GA treated embryos might be expected if they were primed by newly transcribed message induced by the GA, a requirement of the concept of gene depression. Conversely, a reduction in newly transcribed message should be found for ABA. Active message that is newly synthesized should be present on the ribosomes and should therefore be detectable by molecular hybridization to the DNA. We have tested this model by measuring the percentage hybridization of RNA from the ribosome complex of 12 h embryos at saturation levels of the DNA (Fig. 7). The hybrid formed with the newly synthesized RNA accounts for no more than 0·03 per cent of the genome and no differences could be detected among the preparations from control and hormone treated embryos. Chased ribosomal RNA[7] from 48 h embryos was annealed as a check for total rRNA and hybridized to about 0·3 per cent of the DNA. We conclude therefore (*a*) that newly synthesized ribosomes are not yet present in the cytoplasm at 12 h of germination and (*b*) that the mRNA that is active on the ribosomes at 12 h is not newly transcribed. We cannot, however, exclude an effect on the transcription of a small and specific RNA fraction which is below the level of detection by the techniques we have used. Transfer RNA could be such a specific gene product responsible for the stimulation of protein synthesis although other experiments (unpublished) do not support this. We find no evidence that GA or ABA modifies either the levels or the charging of tRNAs during the first 12 h of germination.

Total protein synthesis in germinating wheat embryos can be stimulated *in vivo* by GA and the *in vivo* stimulation is stabilized in the cell free system; direct addition of GA to the cell free system is ineffective. These results suggest the requirement of a cofactor for GA function. This cofactor could be associated with the membranes.

nucleus or cell walls, or it could be readily dialysable, for it is not present in the supernatant, the tRNA or the ribosomal components of the cell free system. Alternatively, it could be highly labile once cells are disrupted.

Hormonal substances evoke their greatest responses when applied to intact cells, although some success in demonstrating regulatory control in isolated organelles has been achieved if the hormone is present during the isolation procedure[23]. Few examples of activity are known for hormones added directly to isolated organelles or to isolated chromatin. In these instances either some fraction of the cytoplasm or a specific protein(s) seems to mediate the activity of the hormone molecules[24-27].

The fact that neither GA nor ABA affects the pattern of monosome and polysome distribution (Fig. 5), while endogenous template activity of the ribosomal fractions from hormone treated embryos is altered (Fig. 6), points to an action of the hormones at the level of messenger availability. The hybridization experiments (Fig. 7), which show that no new mRNA or rRNA is associated with the active ribosomes, indicate that the hormones regulate the use of mRNA already stored in the embryo rather than controlling mRNA synthesis *de novo*.

We conclude that whatever effects the hormones may have on transcription, they are secondary to control at the level of translation, and that, provided the cofactor(s) are available, GA can function in the germination of the wheat embryo by controlling the expression of preformed messages. This could be achieved by unmasking informosomes[28], facilitating the interaction of message with the ribosomes or by regulating the rate of message read out. The action of ABA seems also to be at the translation level, but may be at sites different from those of GA.

We thank Professor G. E. Blackman for interest and encouragement. One of us (D. C.) thanks Sir Isaiah Berlin for a grant from Wolfson College, Oxford.

Contribution of the GABA Bypath to Glucose Oxidation, and the Development of Compartmentation in the Brain

by
A. J. PATEL
R. BALÁZS
D. RICHTER
MRC Neuropsychiatry Unit,
Woodmansterne Road,
Carshalton, Surrey

Post mortem changes in GABA provide a means of assessing the normal GABA flux *in vivo*. Compartmentation involving glutamate and GABA develops with the formation of nerve terminals during the maturation of the brain.

WHEN glucose is oxidized in the brain, a part of the glucose carbon is oxidized in the GABA bypath. Earlier estimates of the magnitude of the GABA flux ranged from 10–40 per cent of the total flux through the tricarboxylic acid cycle, but the methods used were subject to error because of compartmentation or other factors. A more recent estimate obtained by following the oxidation of glucose in brain slices prelabelled with [1-^{14}C]GABA gave the flux through the GABA bypath as 8 per cent of the flux through the tricarboxylic acid cycle[1,2]. GABA formation continues for an appreciable time after death and newly synthesized GABA accumulates in the brain[3]. Assuming the initial rate of GABA formation post mortem is similar to the normal rate *in vivo*, this could offer an independent method of obtaining evidence of the normal GABA flux *in vivo*.

GABA Flux

The post mortem changes in the concentration of GABA and glutamate are shown in Fig. 1*a*. The fractional increase of about 30 per cent at 4 min after death was too small to affect the amount of glutamate in the tissue. The GABA flux *in vivo* was estimated by making assumptions similar to those made by Lowry *et al.*[6] in calculating the *in vivo* rate of energy metabolism in the brain from post mortem changes in metabolite concentrations: first, that reactions requiring O_2 stopped immediately on the arrest of the circulation and, second, that GABA formation proceeded initially at the same rate post mortem as *in vivo*. The GABA flux calculated on this basis, by fitting a regression line to the data, was $0{\cdot}127 \pm 0{\cdot}0196$ (s.e.) μmoles/g/min. The total flux through the tricarboxylic acid cycle may be estimated from the data of Lowry *et al.*[6] and Gaitonde[7] by assuming that 15 per cent of the glucose used was converted into lactate[8] and that the remainder yielded 2 moles of acetyl-CoA per mole of glucose, which were oxidized to CO_2 in the tricarboxylic acid cycle. The flux in the tricarboxylic acid cycle according to these calculations is 1·3–1·6 μmoles/g wet weight/min; the GABA flux was therefore 8–10 per cent of the total flux in the cycle.

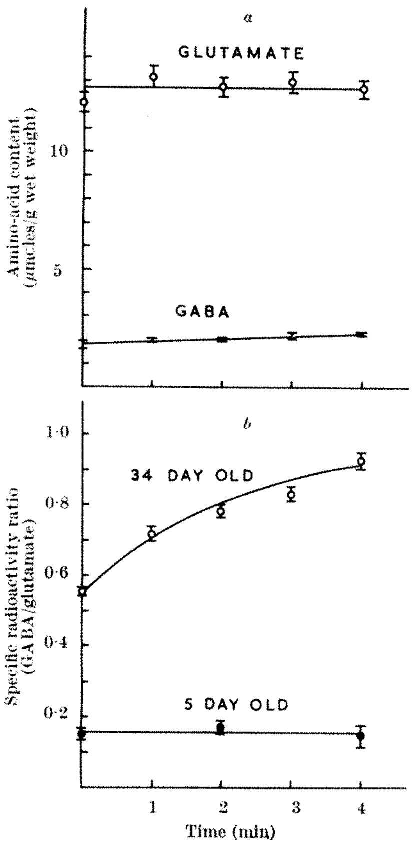

Fig. 1. *a*, Post mortem increase in the content of GABA in the brain of 34 day old albino mice (μmoles/g wet weight). The data were analysed by analysis of variance; the means ± s.e. were plotted (the total number of separate observations was nineteen). Regression lines were fitted to the data. The equation of the line representing the content of GABA per unit weight was $y = 0{\cdot}127x + 1{\cdot}816$; regression coefficient $= 0{\cdot}127 \pm 0{\cdot}0196$ ($P < 0{\cdot}001$). The slope of the regression line for glutamate content was not significantly different from zero: similarly from analysis of variance the values for glutamate content at different times were not significantly different. *b*, Post mortem change in the GABA/glutamate specific radioactivity ratio. The data were analysed and plotted as in *a*; total numbers of individual observations were nine and nineteen for the 5 and 34 day old mice, respectively.

Mice (LAC Carshalton), 5 and 34 days old, received a subcutaneous injection of [2-^{14}C] glucose (52·4 mCi/mmole; dose 20 μCi/100 g body weight). At 10 min after injection one group of mice were killed by immersion into liquid N_2 ("0" time). The other animals were decapitated at the times indicated, brains were quickly excised and the two cerebral hemispheres kept in a humid chamber at 37° C (ref. 4). Three hemispheres of 5 day old mice were pooled for each time-point; one hemisphere from each animal corresponds to the 2 min and the other to the 4 min point. Each time-point in (*b*) is the mean for three sets of pooled tissues. The two hemispheres of the 34 day old mice provided two time-points: each was processed individually. The total numbers of hemispheres used were four at 2 and 4 min, and three at 1 and 3 min. Five whole brains were used for the estimations at "0" time. The metabolic reactions were stopped by freezing in liquid N_2. For the analysis of GABA and glutamate, the brains were extracted with 0·4 M $HClO_4$ and the methods used were similar to those of A. J. P. and R. B. Neutral compounds and carboxylic acids were removed from the acid soluble extracts by a cation exchange resin (Dowex 50, H^+ form). Acidic amino-acids and glutamine were separated by an anion exchange resin (Dowex 1, acetate form). The remaining amino-acids were then adsorbed on a column of Dowex 50 (H^+ form) resin and the neutral amino-acids eluted with 1 M pyridine, leaving the basic amino-acids and ethanolamine on the resin. The neutral amino-acids were processed as described[1]. GABA was separated by paper chromatography (Whatman No. 1; 40 h) using butan-l-ol–propionic acid–water (10 : 5 : 7) and marker strips. The GABA was eluted, a fraction used for determining radioactivity by scintillation spectrometry and another fraction for estimating the α-amino-N content with a Technicon autoanalyser after desiccation.

The absolute value of the GABA flux was higher than that previously estimated using guinea-pig cerebral cortex slices *in vitro*[1,2]; but the relative value was approximately the same as determined before—about 8 per cent of the total flux.

Compartmentation of GABA Formation

A model consisting of a minimum of three compartments is consistent with the data hitherto obtained on the labelling of glutamate and glutamine in brain tissue[1]. Each "compartment" probably results from the summation of a number of different units of more or less similar metabolic pattern. The combination constituting what is defined on a functional basis as a "small" or a "large" compartment[9-11], in view of the size of the related glutamate pool, will depend on the site of entry and metabolism of the substrate considered[1]. The "small" compartment can oxidize a wide range of substrates, including short chain fatty acids and amino-acids, whereas glucose is the main substrate in the "large" compartment[5,9-13]. The "large" compartment has a "sub-compartment" containing glutamate which is apparently the precursor of the "synaptic" pool of GABA (refs. 1, 14 and personal communication from D. Garfinkel).

In these present experiments on 34 day old mice the specific radioactivity of GABA at 10 min after injection of [2-^{14}C]glucose was about half of that of glutamate (ratio 0·55 ± 0·013 [5] at "0" time in Fig. 1*b*). In agreement with Minard and Mushahwar[15], the GABA/glutamate specific radioactivity ratio increased post mortem and at 4 min after death it was almost unity (0·93 ± 0·015[4]) (Fig. 1*b*). Because each experimental animal provided two post mortem time points it was possible to calculate with reasonable accuracy the specific radioactivity of the glutamate from which GABA was formed during the different time intervals after death. The mean specific radioactivity of this glutamate was 54 ± 5 per cent [7] higher than that of the total glutamate in the tissue, confirming the heterogeneity of the "large" glutamate pool.

Development of Compartmentation of GABA Formation

Quantitative morphological studies have shown that the phase of rapid formation of nerve terminals in rat brain occurs during the period from 12 to 26 days after birth[16]. The formation of nerve terminals coincides with the development of metabolic compartmentation in this species[5]. We therefore investigated whether or not the glutamate pool associated with the "synaptic" pool of GABA develops during the maturation of the mouse brain. After administration of [2-^{14}C]glucose the GABA/glutamate specific radioactivity ratio was much lower in the immature 5 day old brain than in the "adult" brain ("0" time in Fig. 1*b*; 0·15 ± 0·016 [3]). By contrast with the results obtained in the "adult" brain, the ratio did not increase during the 4 min experimental period. Thus the glutamate pool, which is the precursor of the GABA formed post mortem, seems to develop at about the time of rapid formation of nerve terminals during the maturation of the brain.

Anti-poxvirus Activity of Rifampicin associated with Hydrazone Side Chain

RIFAMPICIN[1] inhibits the replication of vaccinia virus in infected cells *in vitro* when added at 100 µg/ml. immediately after infection[3,4] or at a late stage of the virus latent period[4]. In the presence of the drug the translation of late viral mRNA species was found to be markedly inhibited 8 h after infection[5]; the rate of late viral protein synthesis declined[6]; the synthesis of the particulate viral RNA polymerase molecules, induced late in infection, was prevented[7]; and the assembly of virions was affected[8,9]. Rifampicin did not affect the synthesis of viral mRNA molecules nor their association with ribosomes to form polyribosomes[5]. The inability of rifampicin to inhibit *in vitro* the activity of the three different species of poxvirus specific DNA dependent RNA polymerases[7] suggested that the mode of antiviral activity of rifampicin differed from its antimicrobial activity. The latter was attributed[10] to the macrocyclic ring of the rifamycin SV molecule which binds to the microbial DNA dependent RNA polymerase and inhibits the initiation of RNA synthesis. Using Shope fibroma virus (SFV), a poxvirus which causes localized tumours in rabbits[11-13], and several rifamycin SV derivatives, we have obtained results which indicate that the anti-poxvirus activity resides in the hydrazone side chain of rifampicin.

Table 1. THE STRUCTURE OF THE SIDE CHAINS AT CARBON 3 OF RIFAMYCIN SV AND THEIR RELATIVE ANTI-POXVIRUS ACTIVITY

Name of compound	Compound No.*	Structure of side chain at position 3	Effect on SFV replication
Rifampicin	31	$-CH=N-\underbrace{N(CH_2)_2N(CH_3)CH_2CH_2}$	Inhibition
—	18	$-CH=N-N(CH_3)_2$	Inhibition
—	11	$-CH=N-C_3H_2NS$	Partial inhibition
—	33	$-CH=N-N(CH_3)CH_2CH_2N(CH_3)_2$	No effect
—	L 8141	$=N-NH\overset{\overset{S}{\|}}{C}NH_2$	No effect
Rifamycin SV	—	$-H$	No effect

* The compound numbers are those of ref. 2.

Our strain of SFV was propagated and assayed first in primary rabbit kidney cell cultures and later in BSC_1 cell cultures and retained the ability to cause tumours in rabbits. The different rifamycin SV derivatives (Table 1), at various concentrations, were added to BSC_1 cell cultures immediately after infection with a low (200–300 p.f.u./plate), or high (10 p.f.u./cell) virus multiplicity, and incubated at 37° C. Isatin-β-thiosemicarbazone (IBT), a potent anti-poxvirus inhibitor[14], was used to inhibit SFV infection at a concentration of 5 µg/ml. The effect of the rifamycin SV derivatives on the development of SFV plaques in infected BSC_1 cell monlayers was studied by adding different concentrations of drug to monolayer cultures which were infected with about 200 p.f.u./plate. The cultures were reincubated for 2 days at 37° C and the plaques in each plate were counted. Table 2 shows that 80 µg/ml. of rifampicin inhibited the development of SFV plaques[4,5]. Compounds 11 and 18 also inhibited the development of SFV plaques but at a concentration of 120 µg/ml., but compound 33, rifamide, rifamycin SV (Table 2), and a thiosemicarbazone derivative (L 8141) of formylrifamycin (recently synthesized by Professor P. Sensi, Gruppo Lepetit, Milan) had no effect on the development of SFV plaques even at 150 µg/ml. On the other hand, IBT (ref. 12) completely inhibited the formation of SFV plaques at a concentration of 5 µg/ml.

Table 2. THE EFFECT OF RIFAMPICIN AND DERIVATIVES ON THE DEVELOPMENT OF SFV

Drug concentration (µg/ml.)	No. of plaques per plate* Drug: 31	11	18	33
0	186	154	154	154
50	131	114	113	145
60	126	183	162	144
70	33	109	142	125
80	0	73	116	146
90	0	—	—	—
100	0	4	12	154
120	0	0	0	177

* Average of six experiments.

The effect of the rifamycin SV and its derivative rifamide on the growth cycle of SFV was compared with that of rifampicin and IBT. Cell cultures were infected with SFV at high multiplicity and immediately treated with the different drugs. We found that synthesis of the new SFV progeny started in the infected cells 12 h after infection and the number of infectious virions gradually increased until 30 h after infection. Addition of rifampicin immediately after infection inhibited the synthesis of SFV, and the amount of the residual virus gradually decreased possibly because of continuation of the uncoating processes (Fig. 1). By contrast with rifampicin, which completely inhibited the replication of SFV and prevented the development of virus progeny, rifamide and rifamycin SV had no effect on the initial steps of the virus replication, but caused a reduction of the final yield of virus. The nature of this effect is not yet clear. Isatin-β-thiosemicarbazone effectively inhibited the synthesis of infectious virions at a level of 5 µg/ml. in contrast to 100 µg/ml. of rifampicin (Fig. 1). Nevertheless, a newly synthesized derivative (L 8141), which had a thiosemicarbazone side chain at carbon 3 instead of the hydrazone molecule, had no effect on the replication of SFV or vaccinia virus. To assess the importance of the hydrazone side chain for the

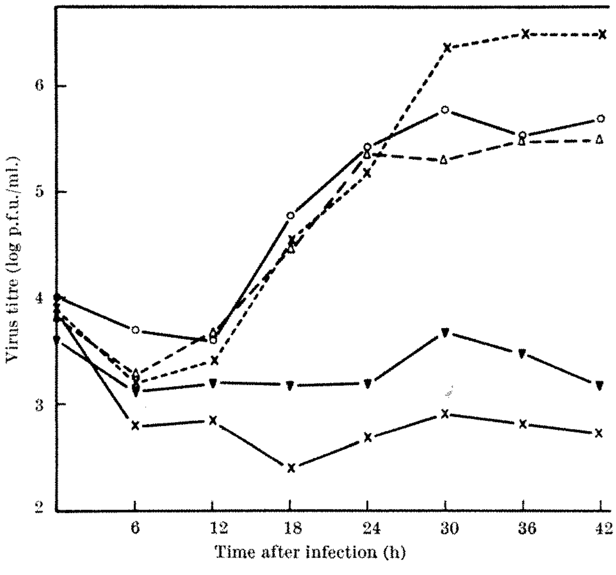

Fig. 1. The effect of rifampicin, rifamycin SV, rifamide and IBT on the replication of SFV. Cell cultures were infected with SFV (10 p.f.u./cell). Part of the cultures was untreated (× - - - ×); the others were treated with rifampicin (100 µg/ml., × — ×); rifamycin SV (100 µg/ml., △ - - - △); rifamide (100 µg/ml., ○—○); or IBT (▼—▼). Samples were removed at different times after infection and the virus yield was determined.

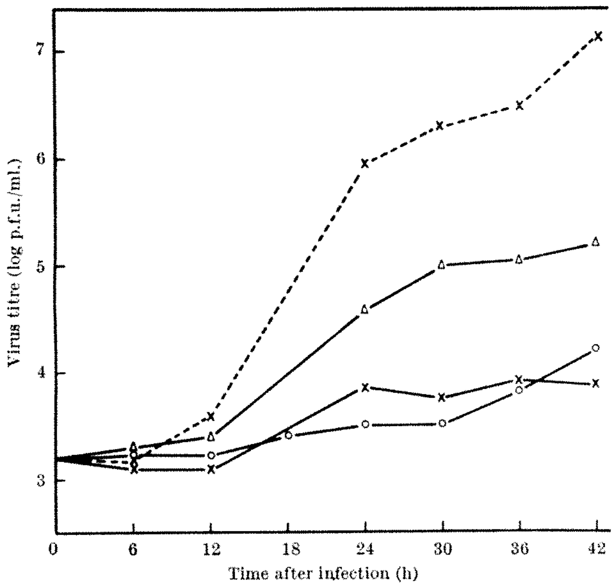

Fig. 2. The effect of compounds 31 (rifampicin), 18 and 11 on the replication of SFV. Cultures were infected with SFV and treated with rifampicin (compound 31, × — ×), compound 18 (○—○), or compound 11 (△—△), each at a concentration of 100 μg/ml. Infected untreated cultures (× - - - ×) were used as controls. The virus yield at different time intervals after infection was determined.

anti-poxvirus activity of rifampicin, the effect of compounds 11 and 18 (Table 1) on the growth cycle of SFV was studied. Compound 33 was not tested because it had no effect on the development of SFV plaques (Table 2). The drugs (100 μg/ml.) were added to the infected cultures immediately after infection. Fig. 2 shows that compound 18 completely inhibited the replication of SFV, as effectively as rifampicin, whereas compound 11 reduced but did not prevent virus replication. Thus compound 18 is a new effective anti-poxvirus derivative of rifamycin SV: both rifampicin and compound 18 were found to inhibit the synthesis of the poxvirus progeny while present in the cells. Washing of the infected, rifampicin treated cells restored the synthesis of SFV virions to a rate similar to that in the infected untreated cultures. Most of the virus progeny was synthesized within the first 24 h after the removal of rifampicin.

These results demonstrate that rifampicin, at a concentration of 100 μg/ml., prevents the replication of SFV in infected cells; SFV resembles vaccinia virus in its sensitivity to rifampicin[3,4]; the inhibitory effect of the drugs persists only as long as they are present in the infected cells; and the hydrazone side chain of rifampicin is responsible for the anti-poxvirus activity of the drug. Removal of the hydrazone side chain from the rifampicin molecule, its replacement by thiosemicarbazone or modifications in the hydrazone side chain causes loss of the antiviral activity. Compound 18, which was found to inhibit SFV, had a low anti-trachoma activity[15,16], whereas compound 33, which lacked anti-poxvirus activity, was found to be a potent anti-trachoma drug[17]. Both rifampicin and compound 18 were found to be less effective in inhibiting SFV than IBT, which is known to affect the binding of late viral mRNA molecules to ribosomes in cells infected with vaccinia virus[18]. A thiosemicarbazone side chain at carbon 3 of rifamycin SV, however, had no effect on the replication of SFV and vaccinia virus. The molecular mechanism by which the hydrazone side chains of rifampicin and compound 18 interfere with the replication of poxviruses is still to be elucidated.

We thank Professor R. Mechoulam (School of Pharmacy, Hebrew University of Jerusalem) for his suggestions, Professor Leo Sachs (Department of Genetics, the Weizmann Institute, Rehovoth) for the strain of SFV and Dr L. Zeller and Professors P. Sensi and L. Silvestri (Gruppo Lepetit, Milan) for the rifamycin SV derivatives. We also thank Mrs Miriam Dreifus for assistance.

Partial Failure of Methylation and Cleavage of 45S RNA in the Blast Cells of Acute Leukaemia

IN animal cells the synthesis of ribosomal RNA follows a definite molecular pattern. The two ribosomal RNA subunits, 28S and 18S RNA, are synthesized in the nucleolus as a large 45S molecule[1,2]. The latter is rapidly cleaved into an 18S molecule and into a 32S molecule. The 18S molecule reaches the cytoplasm immediately. The 32S molecule is converted into a 28S molecule in the nucleolus before reaching the cytoplasm[3].

One of the principal chemical events occurring during this process is the attachment of methyl groups to the 2′ OH of the ribose of ribosomal RNA. The 45S RNA is the main if not the only site of methylation[4,5] so that by studying the distribution of labelled methyl groups in the different types of RNA molecules it is possible to follow the stepwise formation of mature ribosomal RNA. While all the methyl groups incorporated in 45S RNA are preserved during further RNA processing[6], about half of the 45S molecule is lost as RNA maturation proceeds (refs. 6–8).

In rapidly growing cells, such as HeLa cells or phytohaemagglutinin stimulated lymphocytes, the entire process occurs rapidly: the average life of the 45S molecule in HeLa cells is about 15 min. After growing animal cells have been incubated with labelled RNA precursors, the label is found associated with 45S RNA only after short periods of exposure (5–15 min); longer periods bring about an extensive labelling of 28S and 18S RNA.

We have attempted to study the processing of rapidly labelled RNA in blast cells of acute leukaemia, by investigating the sedimentation characteristics of labelled RNA after different periods of exposure to 5-^{3}H-uridine and [^{3}H-*methyl*]-methionine. Homogeneous blast cell populations were obtained from six untreated patients with leucocyte levels ranging from 35,000 to 90,000 per mm^3. Two of these patients had acute lymphoblastic leukaemia; one had acute monocytic leukaemia; three had acute myeloblastic leukaemia. The heparinized blood was

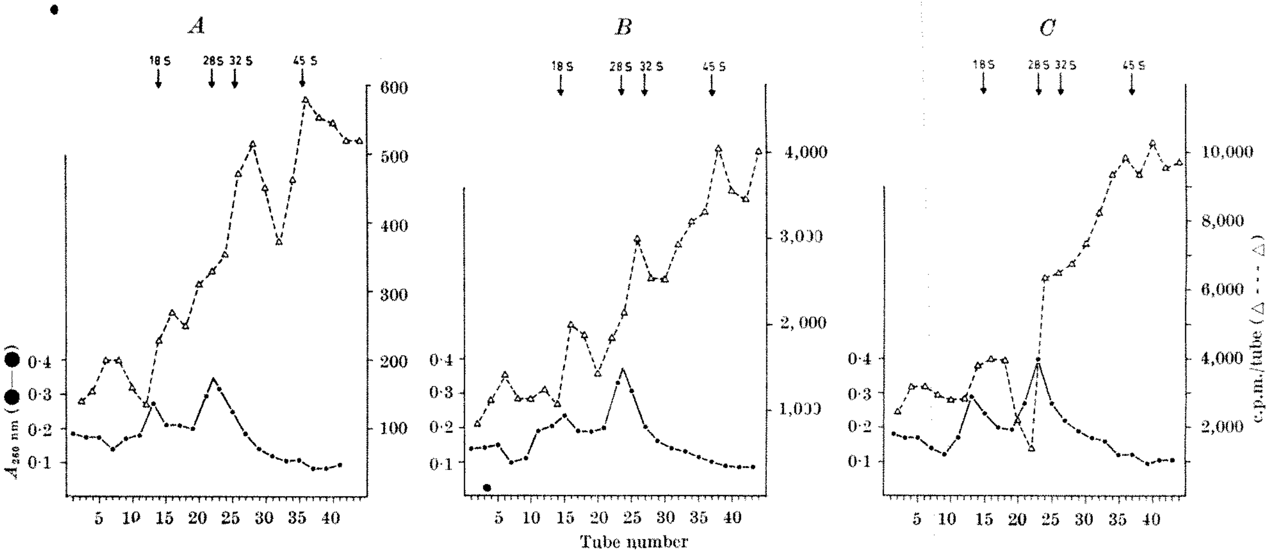

Fig. 1. Sedimentation pattern of labelled RNA extracted from circulating blast cells of patient 1, incubated with 5-^{3}H-uridine (10 µCi/ml.) for 30 min (*A*), 60 min (*B*) and 4 h (*C*). Because labelled blast cell RNA and unlabelled KB cell RNA were extracted simultaneously, the absorbance profile in this and in the following figures represents mainly the unlabelled KB RNA. Gradients were centrifuged at 16,000 r.p.m. for 16 h at 4° C. Approximate S values are indicated.

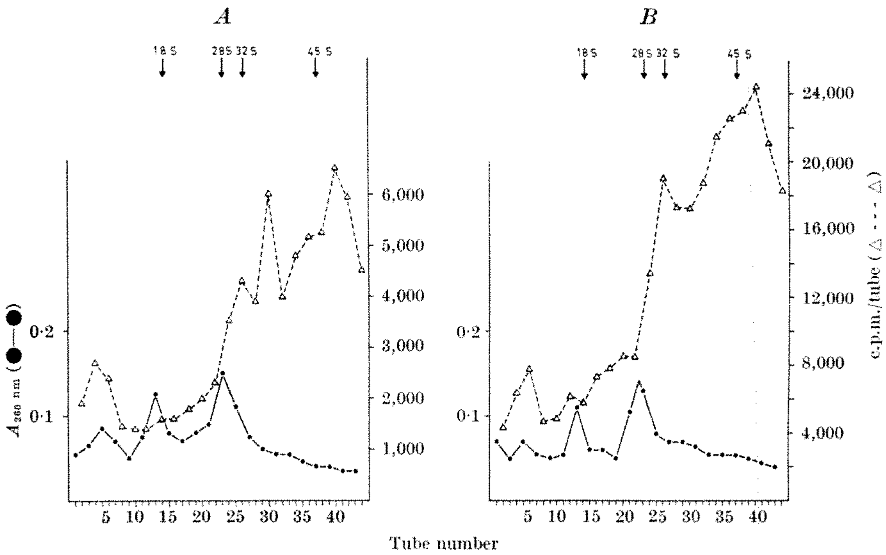

Fig. 2. Sedimentation pattern of labelled RNA extracted from circulating blast cells of patient 2, incubated with 5-^{3}H-uridine (10 µCi/ml.) for 2 h (*A*) and 6 h (*B*). Gradients were centrifuged at 16,000 r.p.m. for 16 h at 4° C.

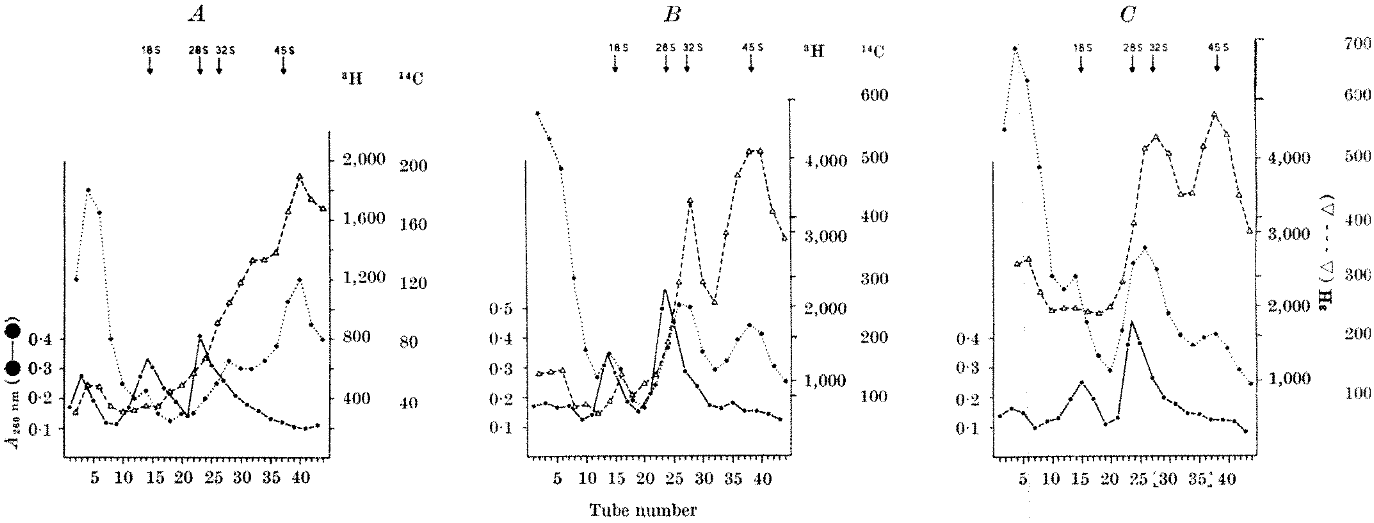

Fig. 3.* Sedimentation pattern of labelled RNA extracted from circulating blast cells of patient 4, incubated simultaneously with 5-^{3}H-uridine (5 µCi/ml.) and [^{14}C-*methyl*]-methionine (5 µCi/ml.) for 1 h (*A*), 3 h (*B*) and 5 h (*C*). Gradients were centrifuged at 16,000 r.p.m. for 16 h at 4° C.

sedimented under gravity, and the leucocyte layer was separated and diluted with minimal essential medium (MEM) and autologous plasma in order to obtain a cell concentration of $5{\cdot}0 \times 10^6$–$8{\cdot}0 \times 10^6$ per ml. with 20 per cent autologous plasma. Cultures (10 ml. each) were set up in rubber stoppered test tubes maintained at 37° C in a rotating system. After periods of incubation with the labelled precursors varying from 30 min to 6 h, the cells were harvested by chilling on frozen saline and centrifuged at 1,200 r.p.m. They were washed once with ice-cold saline. RNA was extracted by a modification[9] of the methods of Scherrer and Darnell[10] and of Kirby[11]. Because of the low number of blast cells used in each experiment, a suitable amount of unlabelled KB cell RNA was extracted simultaneously to act as a carrier. A quantity of RNA (15–30 *A* units) was centrifuged on 5–20 per cent linear sucrose gradients in 0·01 M Tris buffer, *p*H 7·4, at 16,000 r.p.m. for 16 h at 4° C in an '*SW* 25·1' rotor of a Spinco model *L* ultracentrifuge. Forty-five fractions were obtained with a gradient analyser (Isco), and absorption and radioactivity were assayed on alternate fractions[9]. The rate of 5-^{3}H-uridine incorporation was also studied by pipetting at 1 h intervals 200 µl. samples of the cultures in 50 volumes of 5 per cent trichloroacetic acid at 4° C. The precipitate was assayed for RNA radioactivity by a modification[9] of the Schneider[12] procedure.

In all cases studied, irrespective of the cytological type, the results were quite uniform. Incorporation of 5-^{3}H-uridine in acid-insoluble material gave a linear increase up to 7–8 h and decreased slowly afterwards. After short incubation periods (30–60 min) with 5-^{3}H-uridine, most of the radioactivity was associated with RNA with S values higher than 28 and with two main peaks at 32S–35S and 45S–50S (Fig. 1). Furthermore, in most cases, after 60 min incubation, a definite amount of radioactivity was associated with 18S RNA (Fig. 1). These findings indicated that the blast cells were synthesizing and processing ribosomal precursor RNA in a normal fashion, though at a somewhat slower rate. Normal behaviour of ribosomal RNA production would imply that, after longer periods of incubation, most of the radioactive label would be associated with 18S and 28S RNA, and the absorbance and radioactivity profiles would be superimposable. In no case could this be observed. On the contrary, exposure to 5-^{3}H-uridine up to 6 h resulted in an accumulation of radioactivity in the 30S–50S region of the gradient, the peak in 45S becoming extremely prominent (Figs. 1 and 2).

In a study of the distribution of RNA radioactivity after incubation with [^{3}H-*methyl*]-methionine definite peaks of radioactivity were observed at 45S, 32S–28S and 18S, closely corresponding to the peaks observed in the ^{3}H-uridine experiments, thus confirming that synthesis of ribosomal RNA took place in the cells studied. Contrary to the findings in the 5-^{3}H-uridine experiments, it was possible by prolongation of the incubation period to observe a gradual increase in radioactivity in the 32S–28S and 18S peaks, and a proportional decrease in the amount of label associated with the 45S RNA fraction.

We tentatively suggest that in the blast cells of acute leukaemia undermethylated 45S and 32S RNAs accumulate: a substantial amount of the former fails to undergo methylation and cleavage at a normal rate. This conclusion is supported by double-labelling experiments in which blast cells from three of our patients were incubated simultaneously with 5-^{3}H-uridine and [^{14}C-*methyl*]-methionine, and the two isotopes were evaluated in the same RNA fraction. It was observed that the ^{3}H-pyrimidine : ^{14}C-methyl ratio in 45S RNA was increased by prolonging the period of incubation (Fig. 3), thus indicating the accumulation of unmethylated unprocessed RNA molecules.

This investigation was supported by a grant from the Consiglio Nazionale delle Ricerche. We thank Dr Maria Soldati, Farmitalia Research Laboratories, Milan, for a generous gift of KB cells.

Comparison of the Effects of LSD, Heliotrine and X-irradiation on Chromosome Breakage, and the Effects of LSD on the Rate of Cell Division

Cohen, Marinello and Back[1] (1967) first reported that lysergic acid diethylamide (LSD) increased chromosome abnormalities in human leucocytes. Although some later work failed to support this observation[2–4], others have confirmed that LSD damages chromosomes[5–10]. I have investigated the dose–effect relationship of LSD and the type of damage produced in chromosomes of leucocyte cultures of the marsupial *Potorous tridactylus* (rat-kangaroo), which has a few large chromosomes ($2\,n = 12$ in ♀ and 13 in ♂) that make scoring of damage relatively easy and accurate.

I compared this damage with that caused by X-irradiation in the same cell system, and also by heliotrine, a pyrrolizidine alkaloid which is a dangerous hepatotoxin and chemical mutagen[11–14] which damages chromosomes in plants[15,16] and animals[17].

Methods for setting up cultures and assessing cell division have been described before[17]. Fully oxygenated blood was needed for irradiation experiments, and so, to maintain comparable conditions, blood for all experiments was first oxygenated for 30 min[17]. Whole blood was then irradiated (22° C) with 25 r./min (HVL, 0·5 mm Cu; 235 kV peak).

LSD ('Dylisid', Sandoz) was added when the cultures were set up. The smallest dose (0·4 µg/ml.) was chosen on the assumption that 2,000 µg (among the larger doses taken by LSD users) was completely absorbed into the blood stream.

Table 1 shows details of chromosome breakage produced by different concentrations of LSD. All cultures received colcemid at the 72nd hour and were terminated at the 74th hour, except those which received 6·64 µg/ml. of LSD. Because the suppression of cell division at this concentration precluded an adequate estimation of chromosome damage at the 74th hour, treatment with colcemid was prolonged to the 93rd or 96th hour.

Chromatid and isochromatid deletions increased with the size of the dose. All chromosome exchanges observed were of the chromatid type: chromatid dicentrics, triradials and chromatid intrachanges. With the larger

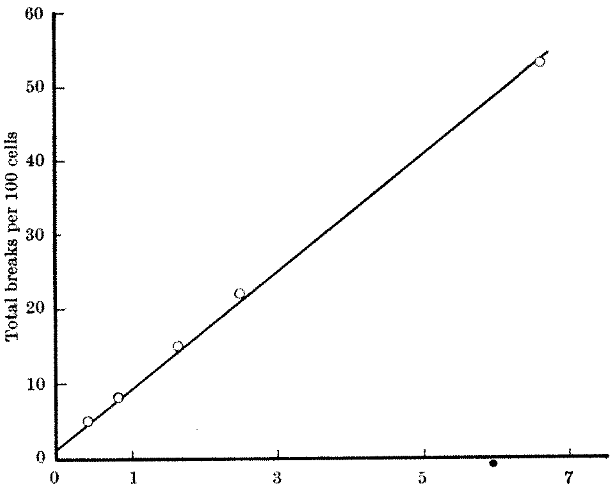

Fig. 1. Effect of LSD on chromosome breakage in leucocyte cultures of *Potorous tridactylus*. Aberrations due to culture conditions have been allowed for.

concentrations of LSD, there was an increase in elongation and attenuation of chromosome material, causing overlapping and difficulties in scoring some of the more damaged cells. This probably led to an underestimate of chromosome damage for the highest concentration of LSD (6·64 μg/ml.). For the range of concentrations used, a linear response was revealed when concentration was plotted against total chromosome breakage (Fig. 1).

Table 1. CHROMOSOME DAMAGE PRODUCED BY LSD IN LEUCOCYTE CULTURES FROM *Potorous tridactylus*

LSD (μg/ml.)	Abnormal nuclei (per cent)	Chromatid deletions (per cent)	Isochromatid deletions (per cent)	Chromatid exchanges (per cent)	Total breaks per cell	Cells scored
0	12	5	9	0	0·14	100
0·145	16	5	12	1·0	0·19	100
0·83	19	9	10	1·5	0·22	200
1·66	25	10	17	1·0	0·29	300
0	13	6	10	0	0·16	100
2·55	30	14	20	2·0	0·38	50
0*	24	15	16	1·0	0·33	100
6·64†	47	31	27	14·0	0·86	100
6·64*	52	39	27	12·0	0·90	100

Final concentration of colcemid was 0·004 per cent.

All cultures except with LSD concentration of 6·64 μg/ml. and the parallel control had colcemid treatment from the 72nd to the 74th hour.

* Cell division arrested from the 72nd to the 96th hour.

† Cell division arrested from the 72nd to the 93rd hour.

Because peripheral lymphocytes usually divide only when stimulated by phytohaemagglutinin, and because LSD was introduced when the cultures were set up, the drug must have been present for the whole cell cycle. Because only chromatid type exchanges were seen, LSD must act on chromosomes only during the period of DNA synthesis (S) or during the post-DNA synthetic period (G_2) when the chromosomes are already double structures. This means that chromosome damage in LSD users cannot be estimated from their peripheral leucocytes, because normally these cells *in vivo* are never at the appropriate stage. The actively dividing stem cells of the lymphoid tissue would be affected, but the more damaged cells would probably not survive to enter the blood stream. Furthermore, because the replenishment of the blood lymphocytes is dependent on many factors, there is no accurate way of determining the numbers of the less damaged cells or the time at which they enter the general circulation after administration of the drug.

Table 2 compares the total chromosome damage caused by LSD, heliotrine and X-irradiation. The total damage done by LSD was of the same order as that produced by heliotrine (1·66 μg/ml. of LSD produced 0·15 breaks/cell; 1·56 μg/ml. of heliotrine resulted in 0·10 breaks/cell). The high concentrations of LSD found in the liver[18] indicate that in habitual users of LSD, liver cells are continuously subjected to the effects of the drug and its breakdown products, for it is eliminated chiefly through this organ. In this connexion it is interesting that heliotrine causes liver lesions, and related pyrrolizidine alkaloids are known to be potent liver carcinogens[19].

Table 2. COMPARISON OF CHROMOSOME BREAKAGE PRODUCED BY LSD, HELIOTRINE AND X-IRRADIATION IN CULTURES OF LEUCOCYTES FROM *Potorous tridactylus*

Treatment	Total breaks/cell	Time of cell arrest (h)	Cells scored
μg/ml. of LSD			
0·415	0·05	72–74	100
0·83	0·08	72–74	200
1·66	0·15	72–74	300
2·50	0·22	72–74	50
6·64	0·53	72–96	100
6·64	0·57	72–93	100
μg of heliotrine*			
1·56	0·10	72–74	100
3·13	0·29	72–74	100
7·80	0·52	72–74	100
15·65	0·95	72–74	100
31·30	1·52	72–74	100
25 r./min of X-irradiation			
100 r.	0·36	72–74	100
200 r.	0·64	72–74	200
300 r.	0·92	72–74	100

* Results for heliotrine damage from ref. 17.

This table takes account of spontaneous aberration due to culture conditions.

LSD resembles heliotrine in preferentially attacking the heterochromatic regions of the chromosomes. With heliotrine, up to 30 per cent of the damaging events occurred in heterochromatin, but for LSD the figure was up to 50 per cent. By contrast, after X-irradiation only 5 per cent to 7 per cent of the total damage occurred in heterochromatin.

It is not possible to equate damage produced by a compound present for the whole of the culture period with that produced by an X-ray dose acting on the chromosomes only at the stage of the cell cycle at which it is delivered. But, as far as comparison is possible, a dose of 100 r. (at 25 r./min) produced a corresponding amount of damage as 4·2 μg/ml. of LSD (Fig. 1 and Table 2). A dose of 100 r. produced 0·0036 breaks/cell/r.[17]. A unit increase of 1 μg of LSD/ml. resulted in 0·078 breaks/cell.

Table 3. EFFECT OF LSD ON RATE OF CELL DIVISION IN LEUCOCYTE CULTURES FROM *Potorous tridactylus*

	Mitotic index as percentage of control				
	Time of arrest of cell division after initiation of cultures (h)				
μg/ml. of LSD	48–51	26–55	72–74	72–93	72–96
0·415	—	41	97	—	—
0·83	—	37	93	—	—
1·66	—	34	85	—	—
1·66 repeat	30	—	82	—	120
2·5	—	—	74	—	—
2·5 repeat	—	—	72	—	148
6·64	—	—	52	125	—
6·64 repeat	—	—	—	—	291

In all, 7,000 cells were scored for every mitotic index estimation.

The effect of LSD on the inhibition of cell division is shown in Table 3. At the 74th hour the higher the dose the lower was the mitotic index; however, in cultures stopped at the 53rd hour inhibition was more acute. At the 74th hour, the cells seem to have been overcoming, to some extent, this effect of LSD. Furthermore, when cultures were stopped in the 93rd or 96th hour, the mitotic index was higher than for corresponding controls. Repeat experiments (Table 3) confirmed that the inhibition of cellular division imposed by LSD was gradually overcome.

It is possible that the concentration of LSD decreases as a result of cellular metabolism, and that cells previously inhibited are released from the mitotic block. Cultures with 6·64 μg/ml. of LSD, however, had at the 96th hour a mitotic index three times that of controls

(Table 3), yet the curve for chromosome breakage did not decline for this concentration (Fig. 1).

These experiments do not rule out the possibility that at later stages of culture, LSD or a breakdown product (perhaps present in minute quantities) stimulates cells to divide. It is interesting that rats treated with LSD in early pregnancy produced, in addition to stunted and stillborn young, some unusually large offspring which weighed more than the young of controls ten days after birth[20].

To investigate this fully, peripheral lymphocytes would be inappropriate, for they have only a finite lifetime in culture. A more permanent cell line would be required.

The concentrations of LSD used in these experiments were greater than would be expected in the blood of users of the drug, for it passes quickly into the tissues and is subsequently eliminated. Some organs, however, contain a greater concentration than that originally present in the blood stream[18]. Human cells may well prove to be less sensitive than *Potorous* lymphocytes, but even a far lower level of damage than that observed here could have far reaching results.

I thank the Australian Institute of Nuclear Science and Engineering for a post-doctoral fellowship. This work was carried out at the Department of Zoology, University of Tasmania, during the tenure of that fellowship.

In vitro Cytotoxic Test for detecting Cell Mediated Immunity to Soluble Antigen

THE demonstration that lymphoid cells from immunized donors are cytotoxic for cells carrying antigens to which the cell donor is sensitized has led to the development of *in vitro* tests for cell-mediated immunity[1]. These systems measure directly the lytic activity of "sensitized" lymphocytes, and can be readily adapted to a quantitative approach by incorporating ^{51}Cr (as sodium chromate) into the antigen-carrying (or "target") cell, and following the kinetics of target cell destruction by measuring the release of ^{51}Cr. This approach has been used most effectively in studies of allograft immunity[2,3]. But in spite of many obvious advantages, these cytolytic tests are generally applicable only to systems involving cell surface antigens, and as such have found particular use in the study of histocompatibility systems. I now describe attempts to extend the applicability of these systems to antigens which are not an integral part of the cell membrane but which are covalently linked to it by the use of coupling agents. Similar previous attempts[4,5] have only yielded systems of low sensitivity.

Adult Hartley strain guinea-pigs were immunized, in the rear foot-pads, with 50 µg dinitrophenylated human IgG (DNP–HGG) in complete Freund's adjuvant. Spleens were removed at various times and a viable lymphocyte population was prepared and counted[2]. "Target" cells were prepared by coupling DNP–HGG to mouse mastocytoma cells (P815) of the DBA strain[6] using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide–HCl (ECDI). These cells were especially chosen for their susceptibility to membrane permeability changes and destruction[7]. They have been found, by several criteria, to be more sensitive to lysis than are erythrocytes (ref. 8 and my unpublished observations).

Mastocytoma cells were collected from cultures in modified Eagle's medium supplemented with 10 per cent inactivated calf serum. The cells were washed twice in sterile Tris-buffered saline and 2·0 ml. of the cell suspension at a concentration of 2×10^6 cells/ml. was incubated with 0·2 ml. sodium ^{51}Cr-chromate (specific activity 100 µCi/µg chromium) for 30 min at 37° C. The suspension was then centrifuged at 1,500 r.p.m. for 5 min and washed three times with sterile Tris-buffered saline. Following haemocytometer counting, using a Trypan-blue exclusion test, 10^6 viable cells were suspended in 1 ml. Tris-buffered saline (*p*H 7·2). A solution of DNP–HGG was passed through a 'Millipore' filter (0·21 µm pore size) and 3 ml. of effluent containing 7·5 mg protein in Tris-buffered saline (*p*H 7·2) was mixed with the mastocytoma cell suspension. One minute later, 0·5 ml. of a 500 µg/ml. solution of ECDI was added. Following inversion, the suspension was left at room temperature for 1 h. The cells were sedimented by centrifugation at 1,500 r.p.m. for 5 min and then washed three times with Eagle's medium containing 10 per cent inactivated calf serum. These "coupled" cells were again counted and cell suspensions adjusted to appropriate concentrations.

"Target" cells (10^5 DNP–HGG coated mastocytoma cells) were incubated at 37° C with 5×10^7 lymphocytes from both normal and sensitized animals. The effects of antigen coupling were assessed by measuring ^{51}Cr release from untreated mastocytoma cells and from the same cells following "coating" with DNP–HGG. After incubation for 1, 3, 6 and 9 h at 37° C, 1 ml. of Tris-buffered saline was added to representative tubes which were then spun at 1,500 r.p.m. for 5 min; 1 ml. supernatant fluid was withdrawn and assayed for ^{51}Cr. The result was corrected for the volume left with the cell sediments, which were also counted for ^{51}Cr, and the amount of ^{51}Cr in the supernatant was calculated as a percentage of the total ^{51}Cr which was originally cell-associated. A typical result, using pooled lymphocyte preparations from three normal spleens and from three spleens obtained from animals 8 days after immunization with DNP–HGG, is shown in Fig. 1. Treatment of the mastocytoma cells with DNP–HGG and ECDI did not affect the rate of ^{51}Cr release over a 9 h period. A further study following ^{51}Cr release over a 20 h period similarly revealed no differences between untreated cells and those exposed to antigen and ECDI. The addition of normal lymphocytes caused only a slight increase in ^{51}Cr release (Fig. 1). On the other hand, the addition of lymphocytes from DNP–HGG immunized animals caused a marked increase in ^{51}Cr release from target cells, more than 30 per cent of radioactive label being released during the 9 h incubation period studied, compared with about 12 per cent for "normal" lymphocytes. (A recent adaptation

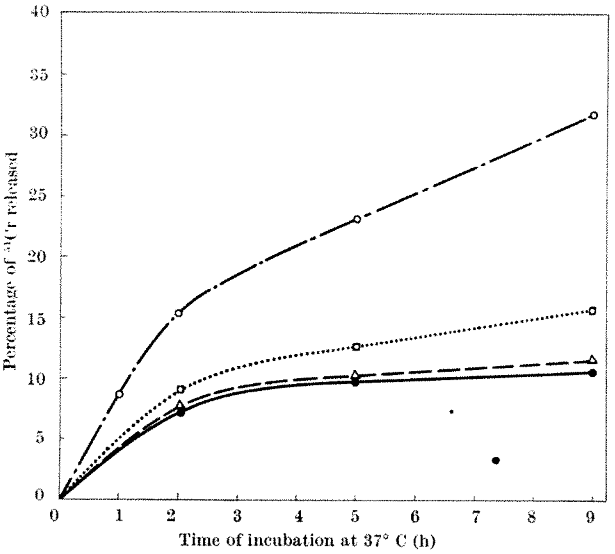

Fig. 1. The rate of ^{51}Cr release from 10^5 mouse mastocytoma cells (●—●), DNP–HGG coupled mouse mastocytoma cells (△ - - △) and from the same number of DNP–Ma cells in the presence of 5×10^7 splenic lymphocytes from unimmunized (□ · · · □) and specifically sensitized (○ - — - ○) guinea-pigs.

in which "target" cells and lymphocytes were gently agitated on a rocking table device has further increased this sensitivity about three-fold.)

The effect of varying the ratio of lymphocytes to target cells in the reaction mixture was investigated by mixing 10^4 target cells with between 10^6 and 3×10^7 lymphocytes from both normal and sensitized animals, in a reaction volume of 0·4 ml. Again, ^{51}Cr release was measured 1, 3, 6 and 9 h after incubation at 37° C. The rate of ^{51}Cr release from target cells was unaffected by the presence of lymphocytes from normal animals (Table 1). There was, however, a direct correlation between the rate of ^{51}Cr release and the number of "sensitized" lymphocytes present: 15·3 per cent was liberated in the presence of 10^6 sensitized lymphocytes (lymphocyte : target cell ratio of 100 : 1), and 33·7 per cent in the presence of 3×10^7 lymphocytes (lymphocyte : target cell ratio 3,000 : 1). The values of lymphocyte : target cell ratios required for extensive lysis in this system are much higher than those observed in systems involving transplantation antigens (compare ref. 7), a finding which almost certainly reflects the low numbers of "sensitized" lymphocytes in the immune spleen following administration of soluble antigen.

Another possible explanation of the rather high ratio of "sensitized" lymphocytes to target cells required for extensive lysis might be that only a relatively small proportion of the mastocytoma cells became "coated" with DNP–HGG in these coupling conditions. Accordingly the antibody induced lysis of DNP–HGG coated mastocytoma cells was studied. To 0·2 ml. (10^5) DNP–HGG coupled mouse mastocytoma cells was added 0·1 ml. of a dilution of guinea-pig antiserum specific for DNP–HGG (approximately 15 μg of antibody). Then 0·1 ml. of a 1 : 2 dilution of fresh rabbit serum was added as a source of complement, and the mixture incubated at 37° C for various times up to 9 h. The rate of ^{51}Cr release was assessed in the usual manner. The cytotoxicity of the antibody and complement preparations was also measured separately (Fig. 2). Lysis by antibody and complement was kinetically very different from that obtained with sensitized lymphocytes (Fig. 1), lysis being complete within 1 h. Lysis induced by either the antibody or complement preparations alone was low. Guinea-pig complement, even in the presence of guinea-pig antibody, was only weakly lytic. These findings (Fig. 2) indicate, however, that at least 80 per cent of the mastocytoma cells have DNP–HGG fixed to their surfaces (this figure can be considered even closer to 100 per cent, for only about 85 per cent of the cell bound ^{51}Cr was released even by distilled water). Thus, unless cytolysis of "target" cells requires a very precise antigenic requirement—for example, a certain number of DNP–HGG molecules on each mastocytoma cell—it seems likely that the lymphocyte : target cell ratios required for cytolysis in this study are high because of relatively low numbers of "sensitized" lymphocytes.

Table 1. EFFECT OF THE CONCENTRATION OF "NORMAL" AND "SENSITIZED" LYMPHOCYTES ON THE RATE OF TARGET CELL DESTRUCTION

No. of lymphocytes in system	No. of DNP–HGG coupled mastocytoma cells (target cells)	Lymphocytes: target cells	^{51}Cr released from target cells after 9 h at 37° C (per cent)

Table 2. SERUM ANTIBODY TITRES AND THE CYTOTOXICITY OF SPLENIC LYMPHOCYTES AT VARIOUS TIMES FOLLOWING IMMUNIZATION OF GUINEA-PIGS WITH 50 μg DNP–HGG IN COMPLETE FREUND'S ADJUVANT

	Cytotoxicity	Serum antibody
Days after sensitization	^{51}Cr released from 10^5 mastocytes by 5×10^7 lymphocytes in 9 h at 37° C (per cent)	DNP–HGG immunoglobulin bound (μg/ml. serum)
0*	12·2	< 20
8	31·8	175
11	29·4	590
24	25·6	1,300
42	22·1	2,800
49	19·6	1,950

* Unsensitized animals (mean of six values).

To assess the cytotoxicity of splenic lymphocytes at various times after immunization with antigen, spleens were taken from groups of animals at intervals following administration of 50 μg DNP–HGG in complete Freund's adjuvant. The amount of ^{51}Cr released from 10^5 target cells by 5×10^7 splenic lymphocytes was assessed following 9 h incubation at 37° C. The capacity of serum samples, obtained at the same time as the spleen excision, to bind

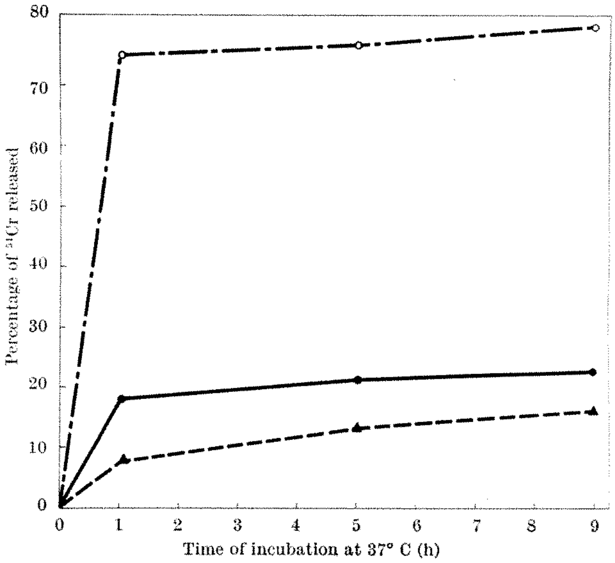

Fig. 2. The rate of ^{51}Cr release from 10^5 DNP–HGG coupled mouse mastocytoma cells by guinea-pig antibody specific for DNP–HGG (▲ - - - ▲) by rabbit complement (●—●) and a mixture of antibody and complement (○ — - — ○).

DNP–HGG was also measured[9] (Table 2). The highest cytotoxic activity was observed between 8 and 11 days after immunization, when serum antibody was low. On the other hand, at a time when serum antibody levels were highest (approximately 6 weeks following sensitization) the cytotoxicity of the splenic lymphocytes, although positive, was rather low. Thus there was no correlation of cytotoxicity with measured serum antibody.

The specificity of the test system was assessed by measuring the cytotoxicity of splenic lymphocytes obtained 8 days after immunization with DNP–HGG for mastocytoma target cells coupled with DNP–HGG, DNP–BSA and HGG. In one experiment, involving pooled lymphocyte preparations from three unimmunized animals and from three spleens obtained 8 days after immunization with 50 μg DNP–HGG in complete Freund's adjuvant, 5×10^7 lymphocytes released 30 per cent ^{51}Cr from 10^5 DNP–HGG coated mastocytoma cells; 22 per cent ^{51}Cr from the same number of DNP–BSA coated cells and 18 per cent ^{51}Cr from the HGG coated cells during a 9 h incubation. The same number of normal lymphocytes released respectively 16, 17 and 15 per cent of the ^{51}Cr from the target cells. When antigens immunochemically unrelated to that used for immunization (for example, BSA) were coupled to the mastocytoma cells, there was no difference between lysis rates in the presence of normal and DNP–HGG sensitized lymphocytes. This indicates that the cytotoxicity has a specificity which is primarily directed against the hapten–carrier complex used for immunization, and as such displays a striking parallel with that of delayed hypersensitivity skin testing in hapten–carrier systems[10].

Further evidence that the cytolytic activity observed here in the presence of "sensitized" lymphocytes was not mediated by serum antibody was the finding that various rabbit antisera specific for guinea-pig immunoglobulins had no inhibitory effect on such lytic activity. The same antisera invariably inhibited lysis mediated by guinea-pig anti-DNP–HGG antibody in the presence of complement. In a typical experiment an antiserum reacting with both the Fab and Fc portions of guinea-pig γ_1 and γ_2-immunoglobulins inhibited >85 per cent the extent of antibody mediated lysis with <2 per cent effect on lysis by "sensitized" lymphocytes.

The modified cytolytic test described here also seems to be specific for cell-mediated immunity, for maximal cytotoxicity was not found to be associated with a maximum serum antibody response. Furthermore, the test was predominantly carrier specific and anti-immunoglobulin antisera failed to cause inhibition of the cytotoxicity.

Because different species may be used to provide target cells and sensitized lymphocytes and as various antigens may be coupled to the target cells, the modified cytolytic test may have general application in the study of cell-mediated immunity.

I thank Dr K. T. Brunner for provision of the mouse mastocytoma cells and for the use of his laboratory facilities, Dr D. S. Rowe for his help, and Miss Katherina Hug for technical assistance.

Chromatography of Proteins on Dipolar Ion Adsorbants

ROUTINE chromatography of proteins was made possible by the introduction of cellulose ion-exchangers[1]. Protein chromatography on ion-exchangers is technically simple but theoretically complex, there being no quantitative theory to act as a guide for experimentation. Proteins are usually unilaterally distributed between the ion-exchange matrix and the surrounding liquid. They are either quantitatively adsorbed ($K_d = \infty$: $R_F = 0$) or not at all ($K_d = 0$: $R_F = 1$)[2]. Finite distribution coefficients are seldom obtained and only in well specified conditions. Gradient elution[3] is used to make the separation of proteins on ion-exchangers practicable, where the distribution coefficients shift from zero to infinity or vice versa in a concentration interval too narrow to be otherwise adjusted. On the other hand, calculation of the shape and position of the gradient effluent is difficult with present ion-exchange systems, for the gradient is altered continuously during passage through the bed.

We believe that it should be possible to make better adsorbants for protein chromatography; they should contain weak adsorption centres with a relatively high density (100–1,000 μequiv/g) and a hydrophilic matrix. Adsorption could possibly be based on ion-dipole interaction where the dipoles attached to the matrix could be dipolar ions. The electrical field potential χ decreases at a greater rate round dipoles than around unit charges. For an isolated dipole and a single charge the quantities are

$$\chi_{\text{dipole}} = \frac{q \cdot l \cos\theta}{D \cdot r(r + l\cos\theta)}\ ; \quad \chi_{\text{ion}} = \frac{q}{D \cdot r}$$

where q is the positive or negative charge of the dipole or the ion, r is the distance from the positive pole (or from the ion) to the position in the field under observation, l is the distance between the two charges on the dipole, θ the angle between the dipole axis and the line to the point in the field, and D is the dielectric constant of the medium.

One advantage with dipole-ion chromatography is that the internal charge shielding can be closely adjusted by changing the dipole distance l. This can be done, for example, by placing a bridge between the charges. The amphoteric nature of the adsorbant can be expected to introduce interesting consequences in the chromatography of amphotytes as well as of ordinary salts. To evaluate the importance of the charge-shielding effect we carried out experiments using ion-exchangers containing the groups $=\overset{+}{N}H-(CH_2)_n-COO^-$ with $n = 1$, 2 and 5. They were prepared by coupling glycine, β-alanine and ε-aminocaproic acid to 'Sephadex *G*–75' by the cyanogen bromide method[4]. Reversible adsorption of the proteins was found to occur and molecular sieving seems to be more prominent with glycine–'Sephadex', while the weak cation-exchanger effect dominates with the β-alanine and ε-aminocaproic acid derivatives.

As a test substance we used cobra venom (*Naja nigricollis*) from which low molecular weight substances were removed by gel filtration on 'Sephadex *G*–25'. Fig. 1 illustrates a fractionation experiment with 100 mg *Naja nigricollis* toxin protein on a 58 × 1 cm column of β-alanine–'Sephadex *G*–75' (750 μequiv/g) in ammonium acetate buffer (*p*H 6).

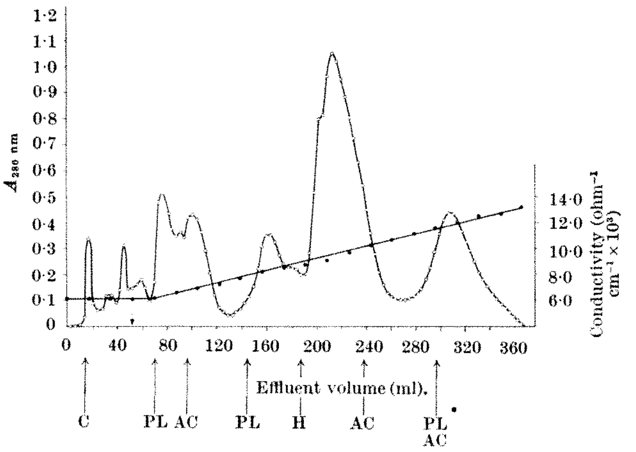

Fig. 1. Chromatography of 100 mg *Naja nigricollis* toxin proteins on β-alanine–'Sephadex *G*–75' (58·5 × 1 cm) in ammonium acetate buffer (*p*H 6·0); starting concentration 0·08 M. Flow rate, 6·8 ml./h. Linear gradient started at arrow. The positions of biological activities are marked below the abscissa: AC, anticoagulant activity; C, coagulant activity; PL, phospholipase; H, hyaluronidase.

The effluent was collected in 3·4 ml. fractions and light adsorption measured spectrophotometrically at 280 nm. The form of the gradient in the eluate was determined conductimetrically. No *p*H changes were observed in the eluate. Some biological activities were determined in or near the peak fractions.

The column referred to in the previous experiment was equilibrated with 0·2 M ammonium acetate buffer (*p*H 6·0) and then eluted with 70 ml. of 0·5 M buffer (*p*H 6·0); there was then a change to 0·12 M buffer (*p*H 6·0). The eluate was collected and the conductivity measured. Equilibration occurs quickly (Fig. 2). Fig. 3 shows a chromatogram of toxin proteins obtained with 0·066 M ammonium carbonate (*p*H 8·0). Most of the proteins move through the column in separated zones and further material is eluted when the buffer is changed to 0·2 M: first there is a displacement peak, and second an elution peak. Representative samples from various parts of the chromatogram were lyophilized and analysed by polyacrylamide electrophoresis. More strongly adsorbed components generally migrated more rapidly to the cathode, although striking deviations occur. Amino-acid analysis was carried out on some of the peak fractions. The arginine content has a dominating influence on the peak position, but a low arginine content can be compensated for by a high lysine content. The marked differences in the distribution of material between the two chromatograms reflects a striking variation in the influence of different structural factors in both the gel and the sample substances.

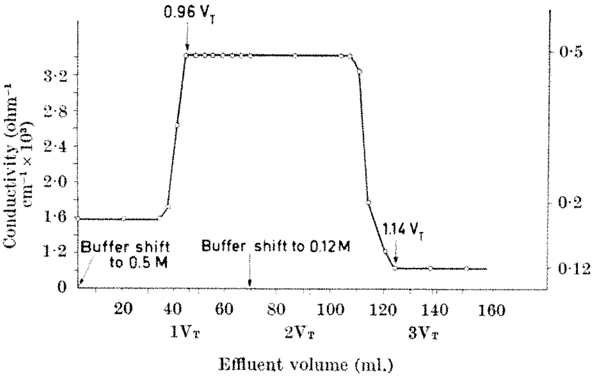

Fig. 2. Equilibration with buffer on a column (58·5 × 1 cm) of β-alanine–'Sephadex G–75'. Ammonium acetate buffer (*p*H 6·0); total bed volume 46·2 cm³.

The dipolar adsorbants have the following useful chromatographic qualities. First, a relative insensitivity to variation in *p*H but a great sensitivity towards ionic strength (which can easily be controlled). Good separation can be obtained using shallow buffer concentration gradients at constant *p*H. Second, suitable conditions—at least for low molecular weight basic proteins—can readily be found for linear chromatography with good reproducibility. Third, high capacity with moderate ionic strengths (with ammonium acetate, for example, ionic strength 0·1) in the *p*H range 4–9. Fourth, in all cases tested proteins can be reversibly adsorbed with moderate changes in buffer concentration or *p*H. The risk of denaturation during chromatography is therefore slight or non-existent. Fifth, equilibration is rapidly attained after buffer changes; the concentration gradient moves through the bed with little delay (Fig. 1). This is of practical importance and may even hold promise for technical development. Sixth, dipolar ion adsorbant beds have a lower tendency to alter in volume on change to another medium than is the case for ordinary ion-exchangers.

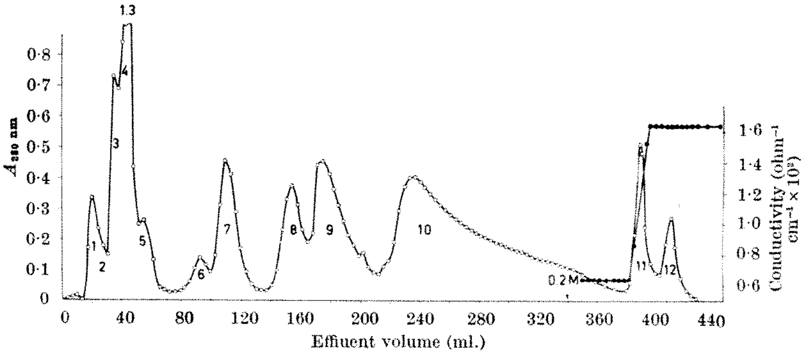

Fig. 3. Chromatography of 100 mg toxin proteins on a column (58·5 × 1 cm) of β-alanine–'Sephadex *G*–75' at *p*H 8·0 in 0·066 M ammonium carbonate buffer.

Improved separation of gram quantities of crude venom may be achieved by chromatography on a larger scale. Possibilities for adjusting the chromatographic operation interval by introducing other types of charged groups, such as guanidino and sulphonate, are being investigated at present. It remains to be seen to what degree dipolar adsorbants can complement or replace the conventional ion-exchangers.

We thank the Swedish Board of Technical Development for financial support and Mr Conny Eklund for assistance. Patents are pending on the technique.

Esterase Activity of Chymotrypsin on O-DNP-L-Tyrosine Ethyl Ester Substrates

WHILE developing a chemical method for the assay of ACTH by dinitrophenylation and subsequent hydrolysis with chymotrypsin, we observed that no di-DNP-seryl-tyrosine could be identified in the digestion mixture by gel filtration on 'Sephadex G-25' column and thin layer chromatography. This suggested that DNP-ACTH is attacked by the enzyme, not at the tyrosyl-2 peptide bond, but at other positions yielding large peptide fragments. The O-DNP derivative of tyrosine may interfere with the action of chymotrypsin on the tyrosyl peptide bond. No work seems to have been reported on the esterase activity of chymotrypsin when the phenolic group of tyrosine is blocked by alkylation or acylation. To verify our hypothesis, model substrates were synthesized in which the phenolic group of tyrosine was blocked by a DNP residue.

N-Acetyl-O-DNP-L-tyrosine ethyl ester was synthesized from N-acetyl-L-tyrosine ethyl ester by Sanger's reagent. A colourless crystalline solid was obtained after recrystallization from aqueous ethanol and had the following characteristics: m.p. 113°–114° C; infrared absorbance peaks, in cm^{-1} (KBr): 1,730, 1,740 (carbonyl); 1,650, 1,600 (amide); 1,560, 1,350, 850 (nitro); found C, 54·46; H, 4·44; N, 9·88—$C_{19}H_{19}O_8N_3$ requires C, 54·67; H, 4·58; N, 10·06 per cent. No hydrolysis of this substrate with chymotrypsin could be detected by a potentiometric method, even after incubation for 12 h, while the corresponding free phenolic compound is the usual substrate for chymotrypsin with a K_m value of $6\cdot9 \times 10^{-4}$ M (ref. 1).

Because this substrate was sparingly soluble in aqueous medium, further evidence was sought by synthesizing a soluble substrate, N-maleyl-O-DNP-L-tyrosine ethyl ester. N-maleyl-L-tyrosine ethyl ester was synthesized by maleylation of L-tyrosine ethyl ester using the procedure of Sheehan *et al.*[2]. An oily product was obtained which could not be crystallized, but which was purified by high voltage electrophoresis in a buffer of pyridine–acetic acid–water (25:1:225, *p*H 6·5), at a voltage of 2 kV for 1·5 h. The pure maleyl derivative was eluted from the paper with acetone yielding an oily material. Its purity was checked by high voltage electrophoresis and thin layer chromatography. This material was directly dinitrophenylated in the usual way giving a colourless solid: m.p. 58°–60° (decomp.); infrared absorbance, in cm^{-1}, (KBr) 1,720, 1,740 (carbonyl); 1,650, 1,600 (amide); 1,560, 1,345, 850 (nitro); found C, 53·03; H, 4·40; N, 8·43—$C_{21}H_{19}O_{10}N_3$ requires C, 53·28; H, 4·02; N, 8·87 per cent. N-Maleyl-L-tyrosine ethyl ester was easily cleaved by chymotrypsin (K_m, $2\cdot08 \times 10^{-2}$M), but the corresponding O-DNP derivative resisted hydrolysis.

These experiments strongly suggest that, for chymotryptic cleavage at the tyrosyl bond, the phenolic group must be free. It would be interesting to test model substrates in which the DNP group was replaced by groups having a negative inductive effect with varying degrees of hindrance.

This research was supported in part by a research grant from the US National Science Foundation. We thank Dr W. R. Slaunwhite for advice and Mrs L. Emerson and Mr F. Maenza for assistance.

Marijuana and Immediate Memory

CLINICAL anecdotes and recent studies suggest that a marijuana "high" interferes with immediate memory (ref. 1, and unpublished manuscripts by L. Clark and A. Wikler). We describe here the effects of calibrated amounts of tetrahydrocannabinol (THC) on cognitive tasks which require immediate memory.

We used THC that had been extracted from marijuana supplied by the Bureau of Narcotics and Dangerous Drugs. Thin layer and gas liquid chromatography of these extracts showed predominantly 1-Δ^1-THC, with some cannabidiol and cannabinol. Quantitative calibrations were made so that doses (20, 40 and 60 mg) were based on the actual content of 1-Δ^1-THC. The doses were in the range which, for synthetic 1-Δ^1-THC administered orally, invariably produces clinical effects approaching those of psychotomimetic drugs, such as lysergide[2,3]. A placebo was composed from an extract of marijuana with cannabinoids removed.

The subjects, who were fasting, received their doses in a randomized order unknown either to them or to the testers. Four oral doses, in 95 per cent ethanol diluted with water, were given on four separate experimental days at least one week apart. The eight subjects were college-educated males in their twenties, weighing between 63 and 85 kg, who had been screened for good physical and mental health. All had smoked marijuana, but at no greater frequency than once a month. They were tested before the drug was given, and at 1·5, 3·5 and 5·5 h afterwards. All testing was done individually in an austere research laboratory.

The digit span task required subjects to repeat, either forwards or backwards, a series of random digits read by the experimenter at a rate of one a second. The span was the longest number of digits that could be reproduced without error on two successive test trials. If the subject's attention waned, the investigator restarted the trial to determine accurately the upper limit of the subject's capacity for that test period.

Table 1. DIGIT SPAN AND THC DOSES TESTED BY ANALYSIS OF VARIANCE (d.f. = 3,21).

THC dose	Means Digits forward	 Digits backward
Placebo	9·0	7·8
20 mg	8·2*	6·9*
40 mg	8·1*	6·6*
60 mg	7·9*	6·4*
F	4·5	5·2
Significant	$P < 0\cdot05$	$P < 0\cdot01$

* These values significantly differ from placebo at $P < 0\cdot01$ by *t*-test for correlative means, 2-tail.

Table 1 shows that significant differences between placebo and each of the THC doses were obtained for both forward and backward digit spans. There were, however, no significant differences between effects of 20, 40 and 60 mg doses, indicating that the smaller dose of THC impairs immediate memory and that larger doses do not significantly augment the impairment. The most significant decrement in forward memory occurred 1·5 h after drug ingestion, with a return almost to the pre-administration result at 3·5 h. For backward memory, there was a greater mean decrement over doses and the impairment was still present 3·5 h after ingestion.

We also gave three subjects a more complicated digit reordering test in two stages. We first read a list of random digits, shorter by two numbers than the subject's forward memory span before he had taken the drug that day, and asked him to recite the digits in the same order. We then instructed the subject to arrange the digits in serial rank order, either upwards or downwards. Each of the three subjects was given at least two reordering tasks during the four testing periods of each experimental day. In the non-drug state (with placebo and before taking the drug), subjects made nineteen errors in forty trials. In the drug state (1·5 and 3·5 h after ingestion for all doses), they made forty-eight errors in thirty-five trials. This difference between the total number of drug and non-drug errors was significant (Mann–Whitney Test).

In the non-drug state, all nineteen errors involved the omission of a given digit or the insertion of one not given. In the drug state, there were thirty-seven errors of this type. In the drug state only, there were also eleven errors in which the subject did not carry out instructions given a few seconds before: for example, he would reorder from low to high rather than follow the instructions to reorder from high to low.

Our observations, like those of others[4], indicate that impairments in immediate memory from marijuana intoxication do not follow a smooth time-function but, rather, are episodic, brief in duration and not always under volitional control. These episodes often interrupted the speech patterns of our subjects and seemed to be associated with the intrusion of extraneous perceptions and thoughts (compare ref. 5). One subject commented: "Well, I just felt very confident and able to remember the numbers . . . then when it came time to give them back, I'd see and hear, mostly see, I think, all kinds of numbers. And I wouldn't know which ones were the right ones." Another subject commented: "I can understand what I'm thinking, but I can't understand what I'm saying. . . . Because there are so many thoughts in between what I'm saying . . .".

The cognitive impairments induced by THC also involve intermittent lapses in attention. One subject stated: "Everything's pretty mixed up . . . I lose track of what's been happening. And it sometimes even seems like a long time has passed, but I know it hasn't, because I'm generally still in the middle of a word or sentence". Because we exhorted our subjects to try as hard as possible, we feel that they were able considerably to mitigate the influence of impaired attention on their cognitive performance. Usually the cognitive changes abated in 3 to 5 h, although some subjects described residual impairment up to 24 h later.

Similar intermittent defects in remembering relevant events may contribute to various types of behavioural disorders, including acute psychoses[6,7]. Elsewhere, we discuss correlations between THC-induced impairments in immediate memory and other behavioural changes[8].

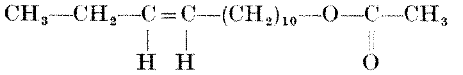
Sex Pheromone of the Oblique-banded Leaf Roller Moth

ALTHOUGH at least ten pheromone compounds have been reported for lepidopterous species, only three[1-3] have proved to be true sex attractants in natural field conditions. We now report that the structure of the sex attractant of the oblique-banded leaf roller *Choristoneura rosaceana* (Lepidoptera, Tortricidae), one of the most widely distributed North American tortricids, is *cis*-11-tetradecenyl acetate (I).



$$\mathrm{CH_3{-}CH_2{-}\underset{\underset{H}{|}}{C}{=}\underset{\underset{H}{|}}{C}{-}(CH_2)_{10}{-}O{-}\underset{\underset{O}{\|}}{C}{-}CH_3}$$

(I)

Two years ago, after identifying the sex attractant of the red-banded leaf roller moth (*Argyrotaenia velutinana*) as (I), we trapped many oblique-banded leaf roller males along with red-banded leaf roller males in orchard traps baited with this compound. We established a laboratory rearing programme for oblique-banded leaf rollers and processed 20,000 female abdominal tips as before[2,3]. At least a hundred-fold increase in free attractant was obtained by saponification of the crude extract followed by acetylation. Identification of the active component was accomplished by the usual techniques[2,3] of column, gas and thin-layer chromatography, ozonolysis and mass spectrometry.

Synthetic compound (I) was very stimulatory to males in the laboratory and has attracted hundreds of oblique-banded leaf roller males in field trapping experiments in the past two years. The *trans* isomer also elicited a response in laboratory bioassays until it was fractionated twice on silver nitrate-impregnated silica gel thin-layer plates to remove traces of the *cis* isomer (I), as was the case for the false codling moth[4]. The *trans* isomer had no inhibitory or masking effects in the laboratory bioassay, but was found to be a very potent inhibitor to male response in the field when added in low percentages to the attractant (I). This emphasizes the importance of field bioassays for biological activities which are not evident in the laboratory.

Because both oblique-banded and red-banded leaf roller males are attracted to the same compound in the field, it is not clear how specificity is effected. The two species have overlapping seasonal and diurnal cycles and share the same host plants. The addition of dodecyl acetate to (I) does effect partial reproductive isolation by drastically increasing attractancy for red-banded leaf roller males[5] and decreasing it for oblique-banded leaf roller males. Preliminary studies indicate that other compounds can give the opposite effect when added to (I) in enhancing oblique-banded leaf roller attractancy and inhibiting red-banded leaf roller response. The emission of different secondary compounds by females of each species along with the sex attractant (I) could effect reproductive isolation in the field for these two species.

We thank F. Wadhams, C. D'Augustine and M. Holland for rearing, sexing and snipping thousands of female moths for this project. This research was supported by a US Public Health Service research grant from the National Communicable Disease Center, Atlanta, Georgia.

Book Reviews

A THEORY OF HUMAN KNOWLEDGE

Genetic Epistemology

By Jean Piaget. Translated by Eleanor Duckworth. (Woodbridge Lectures, Columbia University, 1968.) Pp. 84. (Columbia University Press: New York and London, April 1970.) $5; 45*s*.

In his autobiography Professor Piaget has related how, after his first book on children's reasoning had been published, Einstein asked him to undertake "a developmental study to determine whether the child's intuition of speed depended on a previous comprehension of time and space or whether the former came first"; he found (as he puts it) that "the child is a little relativist, not a Newtonian absolutist". The fruitful suggestion thus thrown out by Einstein turned his attention to what he now calls a "genetic theory of knowledge, i.e. the project of a scientific epistemology based on mental development, both ontogenetic and phylogenetic"; and the problems that emerged formed the starting point for numerous experimental studies carried out by himself and his co-workers at Geneva during the past forty years.

The detailed results have already been set forth in three volumes entitled *Introduction à l'Épistémologie Génétique* (1950); and the four Woodbridge Lectures, now issued in an English translation, present a brief summary of his chief conclusions, and report several new and ingenious experiments confirming his original contentions. The first lecture is chiefly critical. Present-day philosophers, he maintains, tend to treat scientific knowledge as "something final and static"; they either ignore the psychological basis of all human knowledge or improvise a psychology of their own regardless of the actual findings of psychological research. The remaining lectures deal with the formation of such concepts as substance, class, number, time and space. Generally speaking, their gradual development in the mind of the child runs parallel to their gradual evolution during the history of scientific thought. But there are notable exceptions; thus the average child of seven can recognize the topological properties of space, but he does not appreciate Euclidean or projective properties until three years later.

For this reason, so Piaget believes, a merely historical approach may be highly misleading. Why, it is often asked, is *Homo sapiens* distinguished from all other animals by the ability to reason? Because, so it is commonly said, he is endowed with the power of speech. The logical positivists, for example, hold that "all mathematical concepts are derived from logical concepts, and that logical concepts are essentially linguistic structures". Quite wrong, replies Piaget. Observations on both normal children and deaf-mutes reveal that "many logical concepts develop much earlier than, and independently of, language; the idea of number also develops, more or less independently, out of practical attempts to arrange things in visible order". This, as he points out, is in line with Chomsky's contention that "language is derived from reason, not reason from language". But he doubts Chomsky's further assumption that "logical concepts and the ability to reason are innate": "they develop progressively during the first few years of life out of the preverbal coordination of actions; their processes are gradually internalized and so give rise to such conceptual structures as order, number, class and the like".

Piaget, however, explains that he is here concerned solely with the ontogenetic, not with the phylogenetic, development of human knowledge, and therefore refrains from going farther back into comparative biology; if he did so, he might (so it has been argued) find some justification for Chomsky's view. We may certainly agree with Piaget that, so far as individual development is concerned, human knowledge is dependent on, and limited by, the sensory and motor endowment of the human organism. But that endowment must in turn have been developed by natural selection during the evolution of the race.

A human being is a body of moderate size moving about with moderate speeds on dry land, where the objects with which he has chiefly to cope are likewise solid or semisolid bodies of a similarly moderate size, moving (if at all) with similar speeds. In such an environment survival is most effectively secured by a species endowed with vision as the chief distance-sense and kinaesthesis (the muscle-and-joint sense commonly confused with touch) as the sense that chiefly guides his movements. Man therefore tends to interpret the universe in terms of the motion of material bodies moving about in a visible space. Until quite recently this was the source of the basic concepts, not only of common sense, but also of physical science. The revolutionary changes in physics, quite apart from the philosopher's criticisms, have brought home to us how limited and inadequate these concepts really are. As Piaget himself expressed it in one of his earlier papers, "Man's hereditary nervous system and sense-organs are essentially the product of his primitive adaptive needs".

Cyril Burt

LONDON'S COUNTRY

London's Green Belt

By David Thomas. Pp. 248. (Faber: London, March 1970.) 65*s*.

The 846 heavily protected square miles of London's green belt are one of the most remarkable fruits of town and country planning in Britain during the past 25 years. The existence and purpose of the belt seem to be widely known and understood, and politicians believe that they dare not allow a brick to be layed upon its fair green face. A measure of their nervousness is the three years it took to get 400 acres of derelict glasshouses in the Lea Valley allocated to house building between 1963 and 1966. Only the protection of open countryside is pursued with comparable zeal by Britain's planners.

The effect of this care, as Dr David Thomas says in his well researched book, is that the spread of residential and commercial land uses grew by only 0·3 per cent between 1955 and 1960. At that rate, open land in the belt will drop from its present 88 per cent to 82 per cent during the next hundred years. For a stretch of real estate under pressure for development from one of the greatest cities in the world, that is extraordinary.

One gets a sight of what all this means by taking the Bakerloo underground line to Stanmore. There, as you step out of the train, is London *circa* 1938. Barely a thing has changed since. You can walk out of the station, cross a main road, go down a close of quasi-Bauhaus houses, climb over a farm gate and you are in fields. By any standards you are also in an ideal building site.

Dr Thomas describes how the green belt was first proposed at the turn of this century as a pleasure ground for

Londoners or a circular parkway. But it was in the 1930s when Middlesex was disappearing at unprecedented speed beneath bricks and mortar that ideas gave way to action. A sense of urgency was added by the publication of figures about the shortage of playing fields within London and the rate at which potential parkland was being developed on the fringes of the city. These gave strength to Raymond Unwin's 1933 proposal for a thin green girdle which found its political destiny in the London County Council's first Labour administration in 1934. Money to buy open fields and then a special Act of Parliament to protect them appeared during the next four years.

The green belt of today stems from the more extensive one proposed by Abercrombie in 1944. It was given statutory backing between 1954 and 1958, but no sooner had this happened than the Home Counties, ever fearful of London's urban hordes, proposed extending it to cover 2,000 square miles.

Dr Thomas sets out to consider how London might have grown without a green belt but says that there is insufficient evidence on which to theorize. He contents himself with a statistical description of land use changes in the belt and then another one of all the land, urban and rural, in a 10 mile ring around built-up London.

These analyses throw interesting light on things such as the uneven distribution of recreation land, nearly twice as much to the south-west as to the south-east, and on the great extent of the towns set in the green belt to the west of London. Questions about the future of the belt, whether it has impeded London's dynamic, whether it should be turned into a chain of new Royal Parks dotted about with weekend cottages for Londoners, are hinted at but not explored. Dr Thomas leaves the answering of them to the policy makers, which is a pity, but he has provided a useful base from which to start.

TERENCE BENDIXSON

PRESSURES ON THE COUNTRYSIDE

People and the Countryside

By H. E. Bracey. Pp. xx + 310 + 8 plates. (Routledge and Kegan Paul: London, March 1970.) 63*s*.

DR BRACEY has written a comprehensive survey of man's influence on landscape, ranging from the earliest trackways along the chalk uplands to the modern nature trail, from the struggles of a small population to clear forests for agriculture to the demands of a huge population for recreation. Careful scientific studies of the problem of the invasion of the countryside are comparatively recent. How many tramping feet will destroy the marram grass on sand dunes ? What measures can be taken to reduce erosion ? What steps can be taken to lessen the impact of too many people watching too little wild life ? Bracey gives well documented accounts of research on these, now burning, questions.

Bracey looks at every aspect of the countryside, workwise as well as playwise, the repercussions of new industry, railways, bus services, local government and, of course, the effect of new roads and traffic. The internal combustion engine is bringing greater changes to the landscape and the countryside than anything which has happened in all the centuries which Bracey surveys. The straightening and widening of roads, the building of by-passes and car parks, are profoundly affecting our land, and it is essential that some overall policy should be adopted, essential that at some stage road engineers should stop, at least in places such as the National Parks and Areas of Outstanding Natural Beauty, if the character of these is not to be completely changed. Bracey says rather less on this subject, and on the possibilities of traffic management (such as the Goyt Valley scheme), than might have been expected.

There are chapters on dereliction and litter; on the problems of water supply, including the use of reservoirs for recreation; on common land, its present and future use; on the increasing role of forests in providing facilities for recreation, and there is comment on the large part the Forestry Commission has played in pioneering this use. Every chapter is followed by comprehensive notes giving the sources of information. There is, in addition, as an appendix, a list of further reading.

This is a book, as the author himself says, for the thoughtful citizen who sees changes coming rapidly to the countryside and wishes to know what is being, and what can be, done about it. It is also a book for the student and teacher, providing a firm and adequate basis for further research. Bracey's practice of enumerating his points, which he does throughout the book, makes for an easy assessment of the problems, which can then be pursued in more detail. It is a book also for all those concerned with the countryside, planner, forester, water engineer, those in local government and those concerned with leisure. It is certainly a book which should be on many bookshelves; it will, after the initial perusal, be frequently required for reference.

GEOFFREY BERRY

HISTORY OF BRITISH PLANTS

Studies in the Vegetational History of the British Isles

Edited by D. Walker and R. G. West. (Essays in Honour of Harry Godwin.) Pp. 266. (Cambridge University Press: London, April 1970.) 160*s*; $25.

THIS is a book of eleven essays written by thirteen people, all of whom were at some time associated with the subdepartment of Quaternary research in the botany school at the University of Cambridge. The collection is published to mark the retirement from the chair of botany at Cambridge of Professor Harry Godwin, who founded the sub-department and was for many years its inspiration and director. Most of the contributions directly reflect Professor Godwin's own special interests, although it may truly be claimed that it would be difficult to find an aspect of Quaternary research which had not been at some time the subject of original contributions by Professor Godwin himself.

Mention should perhaps first be made of the essay by Professor D. Walker on estimates of rate of change in autogenic hydroseres and of the use by Professor F. Oldfield of evidence from stratigraphical and pollen analyses to investigate the ecological relationships of vegetation at Blelham Bog, because both these contributions recall Professor Godwin's original work in plant ecology and particularly in the ecology of bog and fen. Similarly, Dr J. J. Donner's essay on changes in the relative levels of land and sea in Scotland recalls Professor Godwin's papers on the same problems around the coasts of England and Wales.

The book contains such a wide variety of interests that a short review must unavoidably be superficial or selective. The first essay, by R. G. West, provides a very concise but valuable summary of the history of British vegetation throughout the whole Pleistocene period. It emphasizes the enormous quantity of information that is now available and yet the comparative lack of knowledge of regional variation in all phases earlier than the Late Weichselian and Flandrian, as we must now call the Late and Postglacial periods.

Mrs T. G. Tutin's contribution is also a masterly review and summary of a large amount of information from the English Lake District from which there are now available pollen-diagrams from sixty sites. It must be hoped this will inspire others to write regional summaries. Dr A. G. Smith discusses evidence that Mesolithic man had a greater influence on vegetation than is generally recognized, and Miss J. Turner examines the use of pollen analysis of several profiles in one site to locate local forest clearance and separate it from regional patterns.

Two essays deal specifically with Professor Godwin's interest in the history of the British flora. The essay by Professors G. F. Mitchell and W. A. Watts brings together and discusses knowledge of the history of the Ericaceae in Ireland and of the rarer Irish species in western Europe. Miss A. P. Conolly and Dr E. Dahl present a detailed analysis of the distributions of arctic-alpine and montane species of flowering plants in Britain in relation to the estimated mean maximum temperatures on the summits of the highest hills. This is an extension of Dahl's earlier work in Scandinavia. Where a particular species occurs, the correlations are often remarkable, but many species fail to appear in large areas where summer temperatures seem to be suitable. Why is *Arctostaphylos* not in Wales or on the moors of Devon and Cornwall ? Is it not a little worrying that this plant should favour the warmest south-westerly exposures in most of its English localities and grows in profusion on sunny slopes in the Cevennes associated with *Buxus sempervirens* and *Helleborus foetidus* ? Dare one suggest that if summits more than 3,000 feet above sea-level or corries above 2,500 feet were plotted on a map they might also be correlated with particular limits of mean maximum summer temperature ? One is left with an urgent desire to do some experiments with the plants themselves. C. D. PIGOTT

PLANT CHEMISTRY

Organic Chemistry of Secondary Plant Metabolism

By T. A. Geissman and D. H. G. Crout. Pp. ix + 592. (Freeman, Cooper: San Francisco, 1969.) n.p.

A NUMBER of books similar to this have appeared during the past 5 to 6 years, and although there is nothing excitingly original in this new volume it can be fully recommended. It is well planned, attractively presented, covers a wide field and is relatively free from errors. It represents a solid achievement which will be of great value to the increasing number of organic chemists taking an interest in problems of biosynthesis. It will also appeal to biochemists, not only because of the information provided but also because the biochemical difficulties inherent in biosynthesis are more fully appreciated than they are in some other texts. Indeed, in chapter two the authors give an outline of the biochemical activities which provide the primary building stones for the formation of the complex natural products they discuss. This chapter should be read in conjunction with a biochemical text.

The authors have, on the whole, achieved their claim that "the general principles of chemistry of natural products" have been described "upon which students may build a more detailed and extensive familiarity with one or more of the individual classes that make up the compounds of Nature". From this point of view, the chapters on flavonoids, oxidative coupling of phenols and alkaloids are particularly successful. The chapters on terpenoids are satisfactory as far as they go, but they seem to be less up to date than many of the other chapters. It was unfortunate that in a book whose preface is dated April 1969 it was not possible to mention the discovery of squalene 1,2-oxide as the precursor of triterpenes, or to discuss the basic stereochemical investigations on sterol biosynthesis initiated by Conforth and Popják.

One of the pleasures associated with this book is that almost every time one opens it some statement or comment sets one off on a new line of thought. I, for one, am grateful to the authors for taking the time and trouble to set out in this book their considerable knowledge of and insight into this fascinating field of chemistry. T. W. GOODWIN

TERMITE SOCIETY

Termites

A Study in Social Behaviour. By P. E. Howse. Pp. 150 + 4 plates. (Hutchinson University Library.) (Hutchinson: London, March 1970.) 35*s* boards; 15*s* paper.

THE behaviour of social insects is perhaps too often described in terms of the life of the honeybee. The appearance of an introductory book on termite biology is therefore welcome; as the author says in his preface, many undergraduates know termites better as the home of symbiotic protozoa than as insects. There are disadvantages, however, in approaching sociality in insects through the termites (or for that matter through ants or wasps). The varied life histories of different species compound the complexity which already exists in the life of a single species, and this becomes more serious still when the patchiness of research makes it necessary for discussion to skip from one species to another. Termites are even more tropical in distribution than other social insects and, as a result, have attracted less investigation, except perhaps of an economic kind. Lastly, the developmental stages obtrude more into accounts of social biology in termites than in Hymenoptera; probably most readers will have to turn backwards or forwards to the tables of developmental stages rather frequently.

Dr Howse has been quite successful in meeting these problems. After two slightly repetitive chapters on the habits of termites and elements of termite society, he deals with three aspects of termite life: the swarming and mating of sexual forms, communication by sound and scent and the form, and to a smaller extent the functions and construction of nests. Clearly in some other areas our knowledge is very small; termites are, after all, subterranean and cryptic animals. A more detailed account of tandem formation and of food exchange should, however, have been possible.

The final chapter discusses the relation of some general views of animal behaviour to the social behaviour of insects. This too is successful as far as it goes, but the fact is that our knowledge of the behaviour of termites is at present inadequate for the production of concepts, at least at the "physiological" level which Dr Howse (and I) favour.

The book is adequately but not copiously illustrated, though some illustrations have been marred by over-reduction in size. There are some 170 references and an index. This book can be recommended as a welcome source of information for undergraduates, and others, who are interested in behaviour or entomology.

J. H. SUDD

FISH IDENTIFICATION

Diagnostic des Pièces Rachidiennes des Téléostéens et des Chondrichthyons

1 Gadides. By Georges Desse and Marie-Henriette du Buit. Pp. 71. (Le Expansion Scientifique: Paris, 1970.) n.p.

IDENTIFYING isolated fish vertebrae is a difficult task, even when good collections of comparative material are available. Thus, one should welcome the publication of this new series whose aim is to provide diagnostic characters for identifying vertebrae to the species level.

The first volume is a short, largely pictorial account of various vertebral characters in fourteen species of cod-like fishes from north European seas. The authors have worked out a system of identification based on ossification patterns in the centra, visible externally or in transverse section. The patterns are illustrated by photographs and somewhat schematized line drawings. There are also radiographs (mostly in frontal section) of each element in the entire vertebral column. These are intended to supplement the photographs and drawings (based on one abdominal and one caudal centrum) which form the bases for the diagnostic vignettes.

I have tested out the identification scheme proposed in the book against identified skeletons and with material from an Anglo-Saxon midden. The results were varied, and showed up several flaws, particularly in presentation. For example, no scale is given for any figure (except the radiographs); many of the photographs are so lacking in contrast as to be useless, and the corresponding drawing is often too simplified to be critical. Where the drawings are naturalistic, no account seems to have been taken of individual or ontogenetic variation; indeed, nowhere is there any record of the number of individuals on which the diagnoses were based. Lack of contrast, the small size, and poor quality reproduction greatly reduce the value of the radiographs which, in fact, could be the most useful of all the figures.

In spite of these criticisms, I believe that the system developed by Desse and du Buit could be of great value, especially if in future publications the quality of the photographic reproduction is improved, or the photographs be replaced by good half-tone drawings. For the moment, the worker faced with the need to identify centra will still rely heavily on comparative specimens.

P. H. GREENWOOD

MARINE BIOLOGY

Marine Biology

An Introduction to its Problems and Results. By Hermann Friedrich. Translated from the German by Gwynne Vevers. (Biology Series.) Pp. xii + 474. (Sidgwick and Jackson: London, January 1970.) 70*s* boards; 25*s* paper.

To the modern student of marine biology the sea is presented as a dynamic system, emphasis being given to the interactions between the atmosphere, the oceans and the continental margins which influence the vast production cycles on which its economy is based. This demands a constant awareness of the physical and chemical conditions within the environment, in so far as they affect the biological systems in which the student is interested. This information must be gathered from a wide variety of sources, many written outside a biological context, and in drawing these together in a book, Dr Friedrich has performed a valuable service.

Principally an ecologist, the author gives a short historical introduction dealing with the great expeditions, collecting gear and the major ecological divisions of the sea. This is followed by widely ranging chapters on the adaptations of the plant and animal communities of the pelagic and benthic environments to the physical conditions they experience.

Although he claims the book is written for the non-specialist, it is obviously aimed at the advanced student of marine biology, and the twenty pages of references emphasize the thoroughness with which the author has documented his material. It is particularly useful as a guide to the European literature which might otherwise be neglected through language difficulties.

It is perhaps inevitable that in attempting to cover so wide a field the author's responsibility for independent critical appraisal is sometimes overlooked and the text becomes a mere compendium. For example, Tucker's theories on eel migration are acknowledged but not described, and (p. 166) a remarkable suggestion that the deep-water fish *Opisthoproctus* drifts upside down with its tubular eyes gazing into the depths is accepted without question. My students found the section on temperature/salinity relationships of water masses in relation to animal distribution so brief as to be incomprehensible without consulting the original authors.

Dr Vevers has provided a clear and fluent translation, and the text is well illustrated with 206 figures and 56 tables (including one which has to be inverted to read it). In spite of these shortcomings, the value of the book lies in the presentation of material previously available only as original papers, and at this price the paperback edition represents a real bargain.

DEREK DORSETT

VERTEBRATE BRAINS

Neurobiology of Cerebellar Evolution and Development

Edited by R. Llinás. (Proceedings of the First International Symposium of the Institute for Biomedical Research: AMA Education Research Foundation.) Pp. x + 931. (American Medical Association: Chicago, 1969.) n.p.

THIS large, well produced book is a record of a symposium held only a little more than a year ago. With so much material, some attempt to organize the contributions into a logical pattern was clearly desirable, and this has been carried out partly by grouping the contributions according to phylogeny—one section dealing with fish, one with amphibia and reptiles, and another with mammals. A separate section is devoted to ontogeny, and two papers are included under the heading "Vestibulo-acoustic Input".

The book opens with an introduction, of laudable intention, comprising chapters on vertebrate history (Romer), comparative cerebellar morphology (Elizabeth Crosby) and on the comparative anatomy and physiology of the cerebellar cortex (Llinás and Hillman), and ends with a review by Jansen. The general standard of contribution is high, and one would have no reservations about recommending the volume as a collection of individual papers. Does it not, however, purport to be something more ?

That the fashionable word "neurobiology" appears in both title and preface suggests this, and the inclusion of the chapters by Romer, Crosby and Jansen confirms it. There is, also, the opening of the introductory chapter by Llinás and Hillman: "Since this symposium is dedicated to the study of phylogenetic development of the cerebellum . . ." (p. 43). Such may have been the intention but, inhibited perhaps by the warnings of both Romer and Crosby on the difficulties of extrapolating "lines" of evolution from the data of comparative studies, the participants have in fact produced a series of excellent papers on various aspects of the comparative structure and function of the cerebellum. The contributions that do attempt some generalization or synthesis in the direction of this "dedication" do so from limited viewpoints. Thus Llinás and Hillman conclude that the evolution of the cerebellar cortex becomes readily comprehensible if one contrasts the development of the climbing and mossy fibre systems in relation to the control of Purkinje cells. No attempt is made to correlate such changes with other changes in the organization of the cerebellar system, or alterations in the locomotion of evolving animals. One might object that too little is known to enable us to do this, but that itself is worth demonstrating in this context.

This deficiency is significant enough to highlight the compartmental nature of the text, and brings into question the reason for publishing the proceedings of symposia in this form. From a perusal of the titles and declared intentions of many group meetings of this general kind, one might be forgiven for supposing the point of publishing the contributions as collections to be an attempt to distribute to a wider audience some measure of a synthesis or "state of knowledge" of the topic. Even if one assumes that the participants were able to reach such an enviable state of assimilation, this is rarely, if ever, communicated by the published volume. The present book is no exception, but it must again be stressed that this is no reflexion on the papers read as individual contributions.

K. E. WEBSTER

DRUGS AND SYNAPSES

The Pharmacology of Synapses

By J. W. Phillis. (International Series of Monographs in Pure and Applied Biology. Division: Zoology, Vol. 43.) Pp. xi + 358. (Pergamon Press: London and New York, 1970.) 120*s*; $16.

Our understanding of signalling processes across synaptic junctions in the nervous system has shown exciting progress in the past decade and it is discoveries in this period which the book describes. The author provides a factual and comprehensive catalogue of what is now known of transmission at a wide range of synapses, but the order in which the material is presented is not ideal, with initial chapters on important general characteristics of possible transmitters at all sites. This is followed by chapters on transmission in the peripheral and central nervous systems of mammals and, following this, there is an account of invertebrate and molluscan synapses. This arrangement requires the reader to make frequent back references to obtain relevant metabolic and morphological information.

As a review this book is a notable success and the bibliography is excellent. Where the book fails and frustrates is in not providing interpretations or possible explanations of the frequently controversial information. There are numerous examples of this, for instance, when describing presynaptic transmitter actions, apparently contradictory experiments are quoted without comment or an attempt to equate the anomalies. This lack of critical approach has detracted particularly from the author's assessment of the status of possible transmitters at various sites. The criteria which should now be satisfied by a substance before it can be classed as a transmitter have been listed but have been couched in ambiguous terms and the author does not state which, if any, are essential. This indecision has allowed the author to make strong assertions as to the identity of the transmitters at many sites, including the lateral geniculate nucleus, mitral cells and cerebral cortex, although many important criteria for each example have yet to be demonstrated. As the author himself points out, there are good reasons why extreme caution must be exercised in the identification of a neurotransmitter.

Many of the chapters lay great emphasis on the iontophoretic application of drugs to single neurones and, although some of the difficulties inherent in this technique are mentioned, the unpredictable quantities of many substances ejected is not remarked on. This may explain some of the divergent results which the author has attributed to anaesthetic effects or even to fluctuations in environmental conditions. Other important techniques have often been dealt with in a cursory fashion. Notable gaps occur in the uncritical description of *in vitro* studies and in describing the variety of information available on the evoked release of potential neurotransmitters.

Although the book disappoints in its unbalanced reporting and unimaginative interpretation, there is no doubt that it forms a valuable source of information and provides a most comprehensive and much needed review of a complex and important subject.

J. F. Mitchell

PEROXIDE REACTIONS

The Determination of Organic Peroxides

By R. M. Johnson and I. W. Siddiqi. (Monographs in Organic Functional Group Analysis, Vol. 4.) Pp. ix + 119. (Pergamon Press: Oxford, London and New York, 1970.) 50*s*; $6.75.

Aerobic oxygen reacts with most types of organic compound to give organic peroxides in low concentration. Their structures and properties are almost as diverse as those of the organic monoxy compounds, and a wide variety of methods have been used in their analysis. This book serves as a guide to the most suitable procedure.

After an introductory chapter on the occurrence of organic peroxides, the various types are classified and their reactivities are related to their structures. This is oversimplified: there are some ten different mechanisms by which peroxides can react, and a compound which is unreactive by one mechanism may be very reactive by another.

The various types of chemical and physical analytical methods (for example, iodometric, colorimetric, polarographic and chromatographic) are then discussed. Detailed procedures are quoted for the recommended methods, and examples of their applications are tabulated together with data such as half-wave potentials, R_f values, and retention times. This is a useful, thorough, and critical compilation, and the best source of reference which is available in this field.

There are some shortcomings in nomenclature. Names such as succinic acid peroxide, phthalyl peroxide, and diisopropyl hydroperoxide are not very informative, even if they were used by the original authors. A number of half-truths also occur, which should not be taken at their face value. For example (p. 9), it is stated that "peresters are formed when alcohols react with peracids"; this may be possible in principle, but such a reaction has never been established.

These are minor points, however, and do little to detract from the value of a very useful review.

A. G. Davies

DOWN'S SYNDROME

Measurement of the Facies

A Study in Down's Syndrome. By Michael Joseph and Carol Dawbarn. (SIMP Research Monograph, No. 3.) Pp. xii + 114. (Spastics International Medical Publications in association with Heinemann (Medical): London, 1970.) 50*s*; $7.50.

Dr J. Langdon H. Down, in a paper published in the *London Hospital Reports* for 1866 and entitled "Observations on the Ethnic Classification of Idiots", wrote that a very large number of congenital idiots are typical Mongols; so marked is this that, when placed side by side, it is difficult to believe that the specimens compared are not children of the same parents. Down further wrote that the face is flat and broad, and destitute of prominence; the cheeks are rounded and extended laterally; the eyes are obliquely placed and the internal canthi more than normally distant from one another; the palpebral fissure is narrow, the nose is small.

This classic description of the Mongol child was based on careful clinical observations, but clinical impressions may be inaccurate or misleading and require confirmation by methods involving exact measurements. The research monograph by Joseph and Dawbarn describes an original approach based on painstaking measurements of the face, eyes, nose, mouth and ears, and will prove invaluable to paediatricians and others who may be called upon to diagnose Down's syndrome; furthermore, the techniques can be used to define more accurately other disorders associated with an abnormal facial appearance.

The authors review the attempts from Aristotle (383 to 322 BC) through Albertus Magnus (AD 1192 to 1280), Leonardo da Vinci (1452 to 1519) and Peter Camper (1722 to 1789) to Topinard (1830 to 1911) to measure the human face. These anthropologists and others were interested chiefly in bony landmarks, but the methods devised by Joseph and Dawbarn also take account of the distribution of the soft tissue of the face.

Twenty infants within six months of birth in whom the diagnosis of Down's syndrome had been confirmed cytogenetically were studied in detail, together with twenty normal "control" infants attending an infant welfare clinic. Each infant was photographed in the true antero-posterior and in the lateral position using a 35 mm single lens reflex camera. Each infant was then given a sedative and an impression of the face was made using alginite, alum and plaster bandage, and from this impression a mask was cast. Landmarks agreed by anthropologists were used as points of reference and measured with callipers and the contours were measured with strips of dental wax. For comparative purposes the detailed measurements of facial structure were adjusted to a common age of 190 days. Detailed measurements obtained either from the photographs or from the face mask were made of the general contours of the face, eyes, nose, mouth, ears and facial profile, and the results obtained were compared with those recorded in the literature from 1866 by Langdon Down to Gustavson in 1964.

A few examples will suffice to reveal the exactitude and attention to detail recorded in this monograph. The eye was assessed by the length, angle, asymmetry and shape of the palpebral fissure, by eye size and prominence, by distance between the eyes and by the epicanthic folds. The ear was assessed by length, shape, prominence, lobe and pattern. These and other detailed measurements of facial structures will prove of great value in diagnosis, for they supersede a purely qualitative description and they will be helpful in defining the cardinal features of Down's syndrome and other disorders which have a specific facies. The investigation shows that within their own group the Down's syndrome children are subject to as wide a range of individual variation as normal children.

The authors are to be congratulated on the original, careful and painstaking way in which they have obtained accurate measurements of facial characteristics; their work forms a springboard for extensions of observations by subsequent workers.

R. McL. Todd

ORGANIC REAGENTS

Reagents for Organic Synthesis

Vol. 2. By Mary Fieser and Louis Fieser. Pp. 538. (Wiley (Interscience): New York and London, March 1970.) 160*s*.

The second volume of the Fiesers' book is as welcome as the first. As a result, no doubt, of much correspondence and much searching, many new entries are made dating both from before the deadline of the first volume (1966) and after it. The first volume has lived up to the usefulness I claimed for it in my review (*Nature*, **216**, 1253; 1967); now the second volume containing, as it does, much extra information about reagents already in the first volume will obviously be just as useful. Almost every reagent I set out to look for I found (the exceptions were trichloroethanol and cupric fluoroborate). I look forward to further volumes in what I hope is a series. These books are useful personal possessions as well as essential for a working library.

Ian Fleming

REVISED DURRANT

Introduction to Advanced Inorganic Chemistry

By P. J. Durrant and B. Durrant. Second edition. Pp. xv+282. (Longmans: London, February 1970.) 160*s*.

This is a new and enlarged edition of a book that appeared in 1962. Inorganic chemistry has not remained still in the nineteen-sixties and this book has changed with the times to include plenty of new and up to date material. The authors are husband and wife, a chemist and a physicist, both greatly interested in education and teaching. They have used tables, diagrams, symbols and other devices of presentation which will make the book valuable for students.

The early part is devoted principally to presenting the hypotheses of valency and chemical bonding and the experimental procedures that provide information about atomic and molecular structure. This section includes an interesting chapter on group theory which was not present in the earlier edition. The more theoretical part of the book is much more lengthy and complete than might have been anticipated, but it forms a useful basis for the rest of the book. In the more factual chapters later on in the book, the diagrams, for instance of structures, are good, and considerable use has been made of tables to present a lot of information compactly and to demonstrate similarities and differences.

Since I have had this book in my office and home I have used it for obtaining information several times and it has given good service. I have also found, on these occasions and as I have gone through it, that it is interesting because it derives not only from the knowledge of the authors but also from their attitude and thinking; and this gives the book character.

J. W. Linnett

PRINCIPLES AND ADVANCES

Principles of Radiation Chemistry

By J. H. O'Donnell and D. F. Sangster. Pp. viii+176. (Arnold: London, March 1970.) 45*s*.

Advances in Radiation Chemistry

Vol. 1. Edited by Milton Burton and John L. Magee. Pp. xi+401. (Wiley (Interscience): New York and London, March 1970.) 155*s*.

When a new branch of chemistry can boast a book entitled "Introduction to" and now followed by "Principles of", then I suppose it has achieved a measure of respectability. The authors of *Principles of Radiation Chemistry* argue in the preface that radiation chemistry is now far from being a narrow specialization, and that the study of the effects of radiation on chemical systems provides information about the mechanisms and rates of chemical reactions, particularly those which involve free radicals and ions, which are not readily investigated by conventional methods. The subject is therefore suitable and is increasingly being introduced into undergraduate and graduate courses, to which this book is primarily directed. A difficulty, however, is that the subject has not developed systematically and for many of the diverse systems investigated—organic, inorganic, either in the solid, liquid or gaseous state—often the only unifying factor is that each has been subjected to the influence of ionizing radiation. The chemical effects and mechanisms are often as diverse as is the chemistry of such systems.

Bearing this fundamental difficulty in mind, the authors have succeeded in producing a valuable and concise outline of the entire subject. Following a most extensive survey of the literature sources, the basic modes of interaction of radiation with matter are outlined. There follows a survey of the experimental procedures and special techniques used although, clearly, the fast reaction methods have applications in other areas of chemistry also. The chemical effects are divided into those found in gaseous systems, aqueous solutions, organic compounds and polymerization and graft copolymerization. There is a chapter also on radiation damage in relation to biological systems. Allied studies such as hot atom chemistry and the self-decomposition of labelled molecules are also discussed, and there is a general chapter on the developments such as radiation sterilization and industrial applications which have grown up alongside radiation chemistry.

Yes, the authors have succeeded in a very difficult task, and radiation chemistry generally may well benefit more from this elementary text outlining simply the basic principles than from the many symposia and advanced specialized treatises which have recently appeared.

Advances in Radiation Chemistry is a new series which will be devoted to "developments in the various specialized areas fundamental to theory and experiment in radiation chemistry". This publication follows some 2 years after *Radiation Reviews*, which covers a somewhat similar field, although the latter publication's terms of reference are rather broader than "radiation chemistry". In practice, both publications have published reviews on identical topics already, although only four contributions are included in this first volume of *Advances*. Indeed, one author, Dr J. K. Thomas, has written about the related subjects, solvated electrons and the radiolysis of water, for both review publications. Moreover, one member of the advisory board of *Advances* is himself an editor of yet another review series *Current Topics in Radiation Research*, which also allows reviews in radiation chemistry, although during its development has tended to concentrate on radiation developments more allied to biology.

It would be unrealistic, therefore, not to pose the question whether this subject, barely 30 years old as a discipline, can sustain such a barrage of reviews. Only time, of course, will truly answer this question, but my own view is that provided subjects are critically reviewed and that the frequency of publication is controlled by the developments in any one area, no conflict need arise. This latter point, I note, is also stressed by the editors of *Advances* in their introduction to the series, and as pioneers in the field, they are in an excellent position to view developments with perspective. Even the most obvious duplication, as has occurred with Dr J. K. Thomas's contributions, need present no waste of effort. For example, the author has in the first contribution dealt with a limited aspect of the subject of more current interest, and now given a comprehensive panoramic view of the radiation chemistry of water, which is incidentally of the highest quality. In their own way both reviews can serve a useful function.

Other subjects reviewed in *Advances* are "Charged Particle Tracks and their Structure", by A. Mozumder; "Theory of Transient Negative Ions of Simple Molecules", by Joseph C. Y. Chen and "Chemical Synthesis by Ionizing Radiations", by C. W. Wagner. The first volume, therefore, is disproportionally weighted towards theory, but no doubt future volumes will seek to correct the balance.

Ignoring, therefore, the groans of the librarians and the strains on departmental funds, it is possible to welcome the new venture and wish it well.

GLYN O. PHILLIPS

KINETICS OF CHANGE

Mass Transfer in Heterogenous Catalysis

By Charles N. Satterfield. Pp. xvi + 267. (MIT Press: Cambridge, Massachusetts, and London, February 1970.) 133*s*.

IN presenting a complete revision and extension of his earlier book[1], Professor Satterfield has managed to repeat his tradition of writing a standard text in the field of catalysis. For all those interested in different aspects of the kinetics of catalytic reactions, the book must be required reading.

The general approach is, first, to present the concepts qualitatively, and then to build a quantitative picture on this basis, treating both the simple case and the more complex situations. Theoretical treatments are given, but emphasis remains on their quantitative application to various practical problems of reaction engineering. Several illustrative examples are used throughout the text, and many available experimental data are summarized in tables and graphs.

Molecular diffusion, diffusion in pores and the estimation of diffusion coefficients are considered in the first chapter, together with a brief description of the properties and methods of characterization of solid catalysts. Mass transfer in fixed beds, fluid beds, and various gas-solid-liquid systems is reviewed, and the concept and measurement of effectiveness factors are described. The arguments are applied to simple systems and to more complex cases, particular attention being paid to the influence of temperature gradients in a pellet and to problems introduced by complex kinetics. The final chapter is concerned with the poisoning and regeneration of catalysts and with a short section on the influence of diffusion on selectivity. This book is longer than the earlier volume, the section on mass transfer with chemical reaction having particularly increased in length. It was somewhat disappointing that the discussion of selectivity is still limited to a short section, rather than being treated as a basic concept, and that no discussion of the merits of stirred tank reactors is presented, but these are minor faults.

The book is expensive, but it should interest final year undergraduates, research workers and design and development engineers.

D. L. TRIMM

BASIC OPTICS

Handbook of Gas Laser Experiments

By G. L. Rogers. Pp. 67. (Iliffe: London, March 1970.) 30*s*.

THIS little book is a most timely and useful work which is recommended to all concerned with introducing students to the fascinating world of modern optics. Moreover, those who have entered this field from the disciplines of microwave engineering will especially welcome the pieces of experimental "know-how" which are not part of their training.

It consists of a concise collection of some eleven basic experiments in coherent wave optics.

Brief but sufficient background (with references) is given as an introduction to each experiment and some specimen results are also given. As expected, simple experiments in holography are included; in particular, it is also pleasing to see experiments on the zone plate, Fourier images and Fraunhofer diffraction by single and repeated apertures, thus providing examples of wave phenomena spanning microwave antennas to X-ray crystallography.

ALAN P. ANDERSON

FRINGE PATTERNS

Multiple-Beam Interference Microscopy of Metals

By S. Tolansky. Pp. ix + 147. (Academic Press: New York and London, March 1970.) 45*s*.

THIS book is concerned with principles, experimental techniques and applications of multiple beam reflexion fringes of equal thickness. There are thirteen chapters, together with a collection of references to the work of the author's school, a brief appendix on fringes of equal chromatic order and a useful index.

The principles are treated largely in a descriptive way with a minimum of theory, but there is much useful detail about experimental techniques. The chief value of this book, however, is undoubtedly in the wealth of examples of the use of the beautiful technique of multiple beam surface topography. Professor Tolansky can justly claim to be the sole originator of this simple and elegant method, and in this book we can see some of the great variety of applications which he has pioneered in the past three decades. The following are some of the lesser known applications: electropolished single crystals, loaded ball-bearings, growth spirals on silicon carbide, surface roughness caused by etching on cleaved surfaces, micro-cleavage effects, pile-up round various surface hardness testing indentations, and machining surface quality. The title of the penultimate chapter, "Barton's Button", refers to a historical curiosity, some early 19th century metal buttons which were cast with a coarse grating ruling pattern as a novelty for the dandies of the day; interferometry was used to determine the depth and profile of the rulings. Plastic moulded gratings have recently become available as ornaments on cufflinks, brooches, earrings, and as "skin jewels" for attaching to the forehead, arm cheek, and the like. *Plus ca çhange . . .*

The book is beautifully produced, as one expects from the publisher, and the half-tones of fringe patterns are superb. It can be recommended as an excellent addition to the bookshelf of anybody with an interest in interferometry.
W. T. WELFORD

ATLAS OF THE HEAVENS

Smithsonian Astrophysical Observatory Star Atlas of Reference Stars and Nonstellar Objects

Prepared by the staff of SAO. Pp. ix + 13 + 152 star charts. (MIT Press: Cambridge, Massachusetts, and London, March 1970.) 173*s*.

CONSIDERING the wide range of uses for which charts are needed in optical astronomy, the number available is not excessive. The two most widely used classical atlases are the *Bonner Durchmusterung* or *BD* catalogue and charts (with their southern visual and photographic extensions by the Cordoba and Cape Observatories respectively) and the Palomar Observatory—National Geographic Society Sky Survey, which has no general catalogue and is so rich that it is unlikely ever to acquire one. Astrographic catalogues and charts cover large zones of the sky to 14th magnitude (photographic) north of declination −25°, but have coordinates inconveniently expressed in x and y and no data on galaxies and nebulae, while the Franklin-Adams charts (with no catalogue) provide a poor man's sky survey that is still useful south of the Palomar survey's declination limit at −33°. Other more widely available charts exist (for example, Norton's *Star Atlas* and the Skalnate Pleso atlases by A. Bečvar) and often provide a great deal of useful information, but they are limited either to fairly bright stars or to restricted zones of the sky.

Recent developments in astronomy and space research have increased the demand for rapid access to stars of accurately known position for optical tracking of solar-system objects and space vehicles, for the preparation of finding charts and for the identification of radio, X-ray and infrared sources on the Palomar charts or on photographs taken with large telescopes. The *BD*—an extraordinary achievement in its time and still very useful after 100 years—is virtually complete to the 9th magnitude and has many fainter stars as well, but it has many disadvantages. Its coordinates refer to the epoch of 1855 and often are inaccurate by one or two arc minutes—in some cases even more. Its format is also unsuitable for use at the telescope. At large observatories, the tendency nowadays is to prepare appropriate charts or overlays for an interesting region by computer, using standard catalogues in machine-readable form. But, naturally, these facilities are not always available, and even when they are they may not be usable at short notice, for example, when one is suddenly asked to observe an Apollo vehicle that is getting into difficulties. Consequently the production of a good modern set of charts covering the whole sky, like the present *SAO Star Atlas*, is a very welcome development.

This atlas is designed to be used in conjunction with the *SAO Star Catalog* (1966), which gives accurate positions (epoch 1950·0) and proper motions for some 250,000 stars and is almost complete to the 9th magnitude. (Some fainter stars are also included, but much fewer than in the *BD*.) Thus every star in the atlas (apart from about 1,000 additional stars of unknown proper motion in the South Polar Cap) has a precise position available and so is automatically suitable as a reference star for natural and man-made objects in the solar system or for the preparation of overlays for the Palomar charts and other photographs. In addition, galaxies (with the correct size and orientation), globular clusters, planetary nebulae and NGC objects of other categories are shown, denoted by special symbols. The scale is 0·863 cm per degree, matching that of photographs taken with the Baker–Nunn cameras, and transparent interpolation réseaux enable positions to be read off directly to an accuracy of about one arc minute. Prepared from the *Catalog* with the aid of an analogue computer, the *Atlas* is divided into 152 11 inch × 14 inch charts on stiff paper which can easily be handled at the telescope. This convenience is paid for to some extent by the rather small scale, which makes it advisable to use a magnifying glass, especially in a poorly lighted dome.

At just under 1*s* 2*d* per chart, this excellent atlas is very reasonably priced and it can be most highly recommended to amateur and professional astronomers alike.
BERNARD PAGEL

DECISION MAKING

Decision Theory

By D. J. White. (The Centre for Business Research, University of Manchester.) Pp. ix + 185. (Allen and Unwin: London, November 1969.) 48*s*.

THIS book is essentially a report of the findings of a research project carried out by the author while at the Manchester Business School. The project was concerned with the content of decision theory and its importance in practical decision making. The chief emphasis is placed on an examination of the various concepts which have been introduced in studying the problem of decision. It must be said that the whole subject is only at an interim stage in its development, and there seem to be very few firm conclusions.

A long chapter is devoted to theories of choice, value and uncertainty. Then, after a chapter on decidability, there are some practical considerations in decision analysis. These include a comparison between the physical and human sciences, and it is at this point particularly that one realizes that the subject matter of decision theory consists of a subtle complicated area of human thought which is, at the same time, the concern of the physical scientist, the behavioural scientist, the logician and the philosopher. After a chapter on pragmatic aspects of decision theory, the book concludes with a chapter on mathematical models and decision.

It must be said that the author has written what, to many people, will appear as a learned account of a difficult subject. If anybody hopes that his personal powers of decision making might be improved by reading the book, he is likely to be disappointed. There is no gentle introduction to the subject matter; and, indeed, the first sentence in the text occupies no less than seven lines of print. The reader, if he is to understand the account of value, will have to be able to think of value as an order preserving homomorphism, and to know what is meant by a boolean algebra of sets. Also, in order to understand the discussion of uncertainty the reader will need some knowledge and appreciation of the Heisenberg principle of uncertainty, as expounded in the theory of quantum mechanics. All this is very exciting, but it is only for real scholars, with considerable background knowledge in diverse fields, and with real mental span. It is in the nature of the subject, and the author is to be congratulated on the masterly way in which he has bridged the void between the physical and human aspects of the subject.
L. S. GODDARD

Correspondence

Reprint Request Reflexes

SIR,—I cannot entirely agree with Drs Davies, McKenzie and Turner (*Nature*, May 30) that our spoof letters produced remarkably few reprint requests. My letter to you printed on May 30 was written on April 8 and the number of requests has now reached 111, while a few more come in each week. Requests for the original "middle article", the genuine one, came to 986. If one assumes that this number included about 111 from people who had not read the article (probably an underestimate), then the ratio of "phoney" to "genuine" requests is at least 1 to 8. This ratio varies considerably from country to country; the worst (highest) is from Germany at 16/36, and Czechoslovakia (9/28) where it may be difficult to get the journal. Other continental and Scandinavian countries are much better (14/148) and USA is slightly worse than average (60/434). As one would expect, the ratio for UK and Commonwealth countries is low (8/174), but from these countries came the largest number of jocular cards such as the one from a Dr Sidney Arbour-Bridge . . . not included in the reckoning.

Yours faithfully,

V. R. PICKLES

University College,
Cardiff.

Deservingly Franked

SIR,—I was interested to read the results of recent experiments on reprint request reflexes by Dr Pickles and by Dr Davies and his collaborators (*Nature*, May 30).

My own policy is to send reprints in the first place to friends and colleagues known to be working in the same field and to people requesting them by letter; to people in places I would like to visit; and, of course, to those whose cards bear a pretty stamp.

Yours faithfully,

W. J. MARSHALL

University College Hospital Medical School,
University Street,
London WC1.

Not a Killjoy

SIR,—As the brutes who "pulled up by the roots" the "delicate flower" planted by Drs Davies, McKenzie, and Turner (*Nature*, **226**, 881; 1970), we too regret the apparent failure of their plan to count and identify the corps of foolish reprint-requesters. Objectively, of course, they and Dr Pickles might have been right in ascribing this negative result to *Dateline in Science's* "gratuitous republication" of their original announcements of this intention, so we tried to visualize just how our 125,000 readers—only physicians in active practice, and all of them in the United States—could manage to "do [their] cause no good".

Somehow, the image was blurred: we couldn't imagine very many American physicians reading *Dateline*, suddenly recognizing the impending *faux pas*, and quickly instructing the nurse scanning *Current Contents* not to request that piece on prostaglandins. The population enacting this scenario seems rather limited.

Indeed, Sir, it occurs to us that, if the test failed, it was not because of our "withering blast of publicity" but because of the experimental "design". Assuming one thoughtless pest dispatched a postcard, it may be said that the test succeeded—but would Davies *et al.* and Pickles seriously contend that they could anticipate an optimum or maximum number of such respondents? How then can they claim that *Dateline's* report inhibited any significant portion of an indefinable group? Why then are they disappointed?

Perhaps Turner and his fellow applied mathematicians at Cambridge will devise a workable programme that can really flush out malingerers who acquire reprints to avoid paying 4*s* weekly; should they do so, we pledge to keep their experiment secret.

Yours faithfully,

NAT HALEBSKY

Dateline in Science, Inc.,
575 Madison Avenue,
New York, NY 10022, USA.

Spin-off from Cancer Research

SIR,—I would like to comment on your quotation (*Nature*, **225**, 991; 1970) from *Science is God* by David Horrobin.

Probably it is true that cancer will not be understood until more is known about fundamental processes going on inside the cell. But since the time of Claude Bernard the idea that toxic compounds are useful tools in the study of fundamental processes has often been proved true. To take only one well known example, toxic antibiotics have been widely used to investigate the mechanism of synthesis of macromolecules. Was it ever suggested that actinomycin or puromycin should not be studied until after the synthesis of nucleic acids and protein had been elucidated? Similarly with compounds causing cancer. It was work with carcinogens which led to the discovery of DNA repair enzymes in mammalian cells, and thus revealed the occurrence of unsuspected fundamental biochemical processes. Incidentally, the ingenuity of the experiments is evidence for the scientific ability as well as for the dedication of the scientists concerned.

To mention only one other aspect of the subject, the rate of progress in the study of biochemical events controlling differentiation has been very slow. If cancer is a disease of differentiation, study of how carcinogens cause a change in cell type may help to throw light on this process.

Yours faithfully,

VALDA M. CRADDOCK

MRC Toxicology Unit,
Medical Research Council Laboratories,
Woodmansterne Road,
Carshalton, Surrey.

Gold on the Moon

SIR,—Your Astronomy Correspondent states (*Nature*, **226**, 580; 1970) that the glazing within small lunar craters is an "awkward" discovery. Not so. It is generally our understanding of a new phenomenon which is awkward, or in the wrong direction.

Accepting the cogency of most of Professor T. Gold's explanation, but not the solar flare, I should like to suggest that the source of the radiation was the Earth's ionosphere during the last geomagnetic reversal (700,000 years BP). The energy to heat the ionosphere was derived from the ions accelerated by the new magnetic field increasing from zero. The total energy requirement to glaze the Moon rocks on this hypothesis is less than 10^{-5} that required by the solar flare hypothesis. Two predictions can be made to support this hypothesis: (1) the age of the glazing on the rocks is 700,000 years; (2) the intensity of the glazing effect is diminished with distance from the sub-Earth (sub-Tellurian ?) point on the Moon.

Yours faithfully,

C. W. KAYSING

2244 Sunset Crest Drive,
Los Angeles, California 90046.

Solubility of Life

SIR,—My attention was arrested by a sentence (*Nature*, April 11, 1970) in the paper "Biological Molecules in their Excited States" by Eisinger, Lamola, Longworth and Gratzer, all presumably physicists: "The biologically interesting conditions are, of course, room temperature and aqueous solution. . . ."

A marine biologist might object to "room temperature". But is it possible that physiologists have been treating cells as solutions for so long that physicists are taking it for granted that this is the state of living matter ?

Yours faithfully,

H. R. CATCHPOLE

Department of Pathology,
University of Illinois.

This letter has been shown to the authors of the paper concerned, one of whom replies as follows: *Mea culpa, mea minima culpa!* We physicists should never take sides in arguments between biologists. We were unaware that an issue existed, but we hope the physiologists will not scorn to pursue the hare that Professor Catchpole has started.

Announcements

University News

Four new professorial appointments have been made at **Brunel University: Dr G. C. Bond,** Johnson Matthey and Company, has been appointed to the chair of applied chemistry; **Dr P. Feltham** has been appointed to a new chair of applied physics; **Dr P. Macdonald** has been appointed to the chair of statistics and becomes head of the new Department of Statistics and Operational Research; **Dr T. F. Slater,** University College Hospital Medical School, has been appointed to the chair of biochemistry.

Professor John T. Dunlop, chairman of the University Committee on Governance and a member of the Committee of Fifteen, has been appointed **dean of the Faculty of Arts and Sciences in Harvard University.**

Two members of the faculty of the **Massachusetts Institute of Technology** have been appointed Institute professors. **Professor Arthur T. Ippen** is head of the Water Resources Division of the Department of Civil Engineering and director of the Water Resources and Hydrodynamics Laboratory; **Professor Franco Modigliani** is professor of finance in the Sloan School of Management and professor of economics.

The personal title of professor of tribology has been conferred on **Dr William Hirst,** senior lecturer in the Department of Applied Physical Sciences and head of the Unit on Lubrication and Wear in the **University of Reading.**

Dr J. K. A. Beverley, reader in medical microbiology, has been appointed to a personal chair in the Department of Medical Microbiology, **University of Sheffield.**

The Cancer Research Centre of the **University of Tehran School of Medicine** has been extended to include a hospital unit, to deal with surgery, radiology, haematology and chemotherapy. **Professor A. Habibi** has been appointed director of the new centre, which has been named the **Tadj Pahlavi Cancer Institute.**

Appointments

Mr H. R. Galleymore, manager of the Newcastle Technical Centre, Proctor and Gamble Ltd, has been appointed a member of the **University Grants Committee.**

Dr P. C. Young, head of the Chemical Department of the British Standards Institution, has been appointed first secretary-general of the **Comité Européen de Coordination des Normes.**

The Board of Governors of the **International Atomic Energy Agency** has appointed **Dr Kurt Waldheim,** former Minister for Foreign Affairs of Austria, as chairman of the Safeguards Committee, and **Mr J. A. K. Qartey** (Ghana) and **Academician Brunó F. Straub** (Hungary) as vice-chairmen.

Miscellaneous

Awards from the **Lady Tata Memorial Fund** for research in leukaemia have been made to **T. M. D. Dexter,** Manchester; **D. J. Reen,** Dublin (full-time scholarships); **T. J. E. Rytomaa,** Helsinki; and **B. Szafarz,** Paris (expenses grants); the awards held by **J. F. Dore,** Paris, **Y. Najean,** Paris (expenses grants); **O. Mach,** Prague, and **P. Stryckmans,** Brussels (part-time scholarships) have been renewed for the academic year 1970–71.

In view of the present lack of knowledge of the distribution of seaweed—an important factor in marine pollution—the **British Phycological Society** will collaborate with the **Biological Records Centre** in mapping the seaweed distribution around the British Isles. The first stage will be the collation of record cards which will be sent in by collectors. Those wishing to participate in the scheme as collectors should apply to Dr T. A. Norton, Department of Botany, The University, Glasgow W2.

CORRIGENDUM. In the article "Netherlands: Stop and Go on the Nuclear Merry-go-round" (*Nature*, **226**, 1020; 1970), the figure given in the right-hand column of p. 1021, line 22, should be Dfl. 550,000,000, not Dfl. 550,000.

ERRATUM. An amendment should be made to the erratum (*Nature*, **226**, 782; 1970) referring to the article "Increase in Antiviral Activity of Polynucleotides by Thermal Activation" by E. de Clercq, R. D. Wells and T. C. Merigan (*Nature*, **226**, 364; 1970). The sentence beginning on line 16 of the paragraph following Table 1 should read "Addition of 10^{-3} M EDTA following the 37° C incubation step did reverse the activating effect whereas rapid cooling to 0° C did not".

International Meetings

June 28–July 2, **Health Physics Society Annual Meeting,** Chicago (Professional Associates, 6710 Clayton Road, St Louis, Missouri 63117, USA).

June 29–30, **Optimization Techniques in Circuit and Control Applications,** London (The Manager, Conference Department, Institution of Electrical Engineers, Savoy Place, London WC2R OBL).

June 29–July 10, **The Molecular Basis of Biological Specificity and Control Mechanisms,** Seattle (Battelle Seattle Research Center, 400 NE 41st, Seattle, Washington 98105, USA).

July 3, **Polymer Composites,** Cardiff (Organizer of Short Courses, University of Wales Institute of Science and Technology, 22 North Road, Cardiff CF1 3DY).

July 23–24, **Materials Forming Processes,** Swansea (Dr J. P. Berry, Rubber and Plastics Research Association, Shawbury, Shrewsbury, Shropshire).

August 31–September 3, **Fluid Mechanics and Design of Turbomachinery,** University Park, Pennsylvania (Department of Public Information, Pennsylvania State University, 312 Old Main Building, University Park, Pennsylvania 16802, USA).

September 8–10, **Optical Techniques for Investigations in the Upper Atmosphere,** Exeter (Meetings Officer, Institute of Physics and the Physical Society, 47 Belgrave Square, London SW1).

Sabbatical Itinerants

In the hope of providing some practical assistance in the good cause of mobility between laboratories, *Nature* advertises the needs for housing of families about to take up periods of sabbatical leave. To begin with, no charge will be made for advertisements like this. It is hoped that a period of experiment will show what form these advertisements could most usefully take and whether they are effective.

Wanted: Furnished 3 bedroom house in or near Redhill, Surrey, required by visiting professor and family for 3 months from July 1, 1970. Please contact Mr V. I. Paynter, Personnel Manager, Mullard Research Laboratories, Cross Oak Lane, Salfords, Redhill, Surrey (Telephone Horley 5544).

Wanted: From October 1, 1970, for 6 months, furnished 2 bedroom flat in London with easy public transportation access to the National Hospital, Queen Square, and to Hammersmith Hospital. Please contact Dr C. Bally, Biochemisches Institut der Universität, Zürichbergstr. 4, 8032 Zürich, Switzerland.

Vacant: Modern furnished apartment in Rome (historic centre, adjoining Palazzo Farnese) from September 1970 for 6 months or longer. 3 bedrooms, 2 bathrooms, terrace, central heating, automatic dishwasher. Please contact G. Wolf, Via Giulia 188, Rome 00186, Italy.

British Diary

Monday, June 22

Computing Techniques for Industrial Applications (four-day symposium) Hendon College of Technology, at The Burroughs, Hendon, London NW4.

Kinetic Methods in Analytical Chemistry (6.30 p.m.) Professor H. B. Mark (University of Michigan), Society for Analytical Chemistry, Electroanalytical Group, in the Mechanical Engineering Department, Imperial College, London SW7.

The Conformational Basis of Active Transport in the Mitochondrion (5 p.m.) Professor David E. Green (University of Wisconsin) University College London, in the Botany Theatre, Gower Street, London WC1.

Tuesday, June 23

Early Mammals (two-day symposium) Linnean Society of London, at Burlington House, Piccadilly, London W1.

Wednesday, June 24

Progress in the Application of Data Processing Techniques (2 p.m.) British Institute of Radiology, Nuclear Medicine Committee, in the Barnes Hall, Royal Society of Medicine, 1 Wimpole Street, London W1.

Protein Binding of Antibodies (2 p.m.) Dr G. Robinson, University of London, at the Royal Postgraduate Medical School, DuCane Road, London W12.

Thursday, June 25

Automation in Haematology (5.15 p.m.) Dr B. E. Gilliver, University of London, in the Page Street Lecture Theatre, Westminster Medical School, Horseferry Road, London SW1.

The Electrical Control of the Human Heart (5 p.m.) Dr Edgar Sowton, University of London, at the Institute of Cardiology, 35 Wimpole Street, London W1.

Trace Analysis (two-day meeting) Society for Analytical Chemistry, Scottish Section, jointly with the North East Section ; and the Atomic-Absorption Spectroscopy and the Radiochemical Methods Groups, at the University of St. Andrews, St. Andrews, Scotland.

Friday, June 26

The Earth, Professor Sydney Chapman, FRS; **The Sun and the Interplanetary Medium,** Professor D. E. Blackwell (11 a.m.–1 p.m.; **The Stars and the Structure of the Galaxy,** Sir Richard Woolley, OBE, FRS; **Extra-Galactic Nebulae,** Professor Sir Martin Ryle, FRS; **Astronomy of the Future,** Professor H. Bondi, FRS (2.15–6 p.m.), Royal Astronomical Society, at the Royal Institution, Albemarle Street, London W1 (Sesquicentenary Celebration Lectures).

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

***2 MONTHS** (52 issues and 4 indexes)

Great Britain and Eire	**£14 0 0** each
United States of America (by air freight)	**$48** each
Canada (by air rfeight)	**$52** each
Elsewhere overseas by surface mail	**£14 0 0** each

(Charge for delivery by air mail on application)

*Shorter periods *pro rata*. (Minimum three months.)

The EM 801 Electron Microscope gives you

6 sp[redacted]cim[redacted]n changes in seconds!

The EM 801 Electron Microscope has been designed and built by AEI to give biologists the results *they* need. First of all, extraordinary Specimen Handling Facilities. Only 90 seconds to change a cartridge holding 6 specimens: to insert a holder for serial section examination, or to tilt specimens ±20°, or ±30°. In every case, *without altering either objective focal length or resolution.* All holders can be electrically driven at controlled speed, and can be plugged in immediately without breaking the main vacuum.

In addition, guaranteed point-to-point resolution of 5 Å.

This superbly designed instrument is one of many developed by AEI to assist you in the conduct of your research, with the accuracy and precision you have a right to expect from truly scientific apparatus. Above all, the EM 801 provides the facility to give you results without fuss, and *without the need to dismantle any part of the instrument.*

Fill in the coupon and we will send you an informative booklet with full details of this and the wide range of AEI Electron Microscopes.

As eas[redacted] as you [redacted] fill in th[redacted]s coupo[redacted].

I would like to know more about your Electron Microscopes. Please send me your booklet.

I am interested in their use for: ☐ Biology. ☐ Crystallography. ☐ Metallurgy. *Tick box as applicab*

APPOINTMENTS VACANT

UNIVERSITY OF EDINBURGH

DEPARTMENT OF ZOOLOGY

BIOCHEMIST

required as Research Associate in a three-year investigation of the role of proteins in plasma membrane structure, in the above Department. Previous experience in protein chemistry an advantage.

Salary scale: £1,355 to £1,605 per annum according to qualifications, together with F.S.S.U.

Applications, giving the names of two referees, should be sent to Dr. A. H. Maddy, Department of Zoology, University of Edinburgh, West Mains Road, Edinburgh, EH9 3JT. Please quote reference 1060. (2426)

MEDICAL RESEARCH COUNCIL

VETERINARY MICROBIOLOGIST

(age 28-35) required for Scientific Staff of the Council's Laboratory Animals Centre. Candidates must be interested in laboratory animal medicine and be prepared to specialise in the microbiology and pathology of laboratory animals.

Previous experience in this new veterinary field would be an advanage in joining a team headed by a veterinary pathologist for whom the successful applicant will be expected to deputize when necessary.

Duties will include responsibility for the microbiological screening (including for some viruses) of germfree and specific pathogen free colonies, leading to the development of animals with a more accurately defined flora.

The post carries responsibility and offers unique opportunities for the successful applicant.

Excellent conditions of service. Starting salary normally within the range £1,175 to £2,275 and £2,455 to £2,930 in accordance with age, qualifications and experience; F.S.S.U., London allowance £60 ; six weeks annual leave.

Applications to the Director, M.R.C. Laboratory Animals Centre, Medical Research Council Laboratories, Woodmansterne Road, Carshalton, Surrey.

(2311)

UNIVERSITY OF LONDON

CHAIR OF ZOOLOGY AT BEDFORD COLLEGE

The Senate invite applications for the Chair of Zoology tenable at Bedford College. Salary not less than £4,120 a year plus £100 London Allowance.

Applications (10 copies), must be received not later than July 10, 1970, by the Academic Registrar, University of London, Senate House, W.C.1, from whom further particulars may be obtained. (2440)

CSIRO

POSTDOCTORAL RESEARCH FELLOW (CHEMICAL ENGINEER)

AUSTRALIA

DIVISION OF CHEMICAL ENGINEERING

GENERAL The Division of Chemical Engineering of the Commonwealth Scientific and Industrial Research Organization undertakes fundamental studies of selected unit operations and their application to the chemical and process industries, including general process development. The Division has recently taken occupation of extensive new laboratories at Clayton, Victoria, adjacent to Monash University, about 12 miles from Melbourne. Powerful analogue, digital and hybrid computing facilities are available.

DUTIES The appointee will be required to join teams engaged on work on one or other of the following fields:

(a) Studies of gas-solid fluidisation in large scale equipment. The work would involve experimental and theoretical studies inter alia of, the effect of distributor design on gas and solids motion in beds of up to 64 ft^3 cross section.

(b) Studies of heat transfer in relation to water desalination by distillation, food poisoning etc. Present work includes fundamental studies of boiling heat transfer in film flow, and heat transfer to oil/water systems.

QUALIFICATIONS Applicants should have a degree in chemical engineering or applied science, together with a Ph.D. degree or post-graduate research experience of equivalent standard and duration, supported by satisfactory evidence of research ability. Experience in one or other of the above fields would be of value, but is not essential.

SALARY Depending upon qualifications and experience, the appointment will be made within the salary range of Research Scientist, $A6,139–$A7,789 p.a., or Senior Research Scientist, $A8,105–$A9,448 p.a. Salary rates for women are $A428 p.a. less than the corresponding rates for men. Promotion within CSIRO to a higher classification is determined by merit.

CONDITIONS The appointment will be initially for a fixed term of three years, after which, if mutually desired, either an extension of tenure or appointment for an indefinite period will be considered. The appointment will be conditional upon passing a medical examination and an initial probationary period of twelve months may be specified. An indefinite appointment carries with it Commonwealth Superannuation Fund or Provident Account privileges. Further details supplied on application.

Applications, (quoting Appointment No: 608/120), and stating full name, place, date and year of birth, nationality, marital status, present employment, details of qualifications and experience, together with the names of not more than four persons acquainted with the applicant's academic and professional standing, should reach:

Mr. R. F. Turnbull,
Chief Scientific Liaison Officer,
Australian Scientific Liaison Office,
64–78 Kingsway,
LONDON, WC2B 6BD. by the *7th August, 1970.*

Applications in U.S.A. and Canada should be sent to The Scientific Attaché, Australian Embassy, 1601 Massachusetts Ave. NW, WASHINGTON DC 20036.

(2474)

UNIVERSITY OF WALES

UNIVERSITY COLLEGE OF SWANSEA

ASSISTANT LIBRARIAN

Applications are invited from graduates, with professional training and/or appropriate experience, or from non-graduates with A.L.A., for the post of Assistant Librarian (Science) in the College Library.

The salary will be either within the preliminary scale £1,200 to £1,355 per annum or £1,355 to £2,230 (bar) per annum according to qualifications and experience, with the prospect, in the case of graduates, of extension to £3,105 per annum.

Further particulars, quoting reference number B6 may be obtained from the Registrar, University College of Swansea, Singleton Park, Swansea, Glam., SA2 8PP, by whom applications should be received not later than **Monday, July 13, 1970.**

(2503)

IMPERIAL COLLEGE

(UNIVERSITY OF LONDON)

DEPARTMENTAL LIBRARIAN

Applications, from graduates or others with relevant experience, are invited for the post of Librarian of the Biochemistry Department Library of Imperial College. The Library is shortly to move into a new building and will be run in conjunction with the Chemistry Department Library. The appointment will be made at the Assistant Librarian III Grade and the salary will be in the range £1,100 to £1,800 per annum, plus F.S.S.U.

Applications with full curriculum vitae and the names of two referees should be made as soon as possible to Professor Sir Ernst Chain, F.R.S., Department of Biochemistry, Imperial College, London S.W.7. (2502)

Overseas Development

The provision of skilled manpower is a vital element in Britain's aid to the developing countries. Your professional skills are needed overseas and you will have the satisfaction of doing a challenging, responsible and worthwhile job. Terms of service usually include substantial extra benefits including family passages, paid leave, educational grants and free or subsidised accommodation. For certain of these appointments an appointment grant of up to £200 and a car purchase loan of up to £300 may be payable. Salaries are assessed in accordance with qualifications and experience. In most cases the emoluments shown are based on local salary scales plus basic allowances. Appointments are on contract for 2-3 years in the first instance, unless otherwise stated. Candidates should be citizens of, and permanently resident in, the United Kingdom.

PRINCIPAL FISHERIES SCIENTIST
£2,645-4,375/Saudi Arabia

To participate in establishing and equipping a Marine Research Centre and to assist in planning and supervising a five year research programme as part of a team sponsored by the University College of North Wales and the Saudi Arabian Ministry of Agriculture and Water. Candidates must have a PhD in marine biology with at least three years' experience in fisheries research and preferably organisational experience in marine research and familiarity with tropical waters. Emoluments quoted above include a variable tax free overseas allowance of £645-1,375.

RESEARCH OFFICER (BIOLOGIST)
£1,754-2,669/East Africa

To conduct an investigation of the tunas of commercial importance in East African waters. He must have a good honours degree in a zoological subject and research experience in marine fisheries. Emoluments quoted above include an inducement allowance, normally tax free, of £732-926. A terminal gratuity of 25% of the total emoluments is also payable.

ASSISTANT CONSERVATOR OF FORESTS
£1,636-2,876/Malawi

To administer a forest area or undertake an assignment in any specialised branch of the Forest Department. He must have a degree in forestry. Emoluments quoted above include a supplement, normally tax free, of £216-276. A gratuity, normally tax free, of 25% of emoluments (excluding supplement) is payable on completion of tour of not less than 30 months.

FISHERIES BIOLOGIST
£3,160-4,410/Jamaica

To investigate aspects of fisheries biology, to recommend what fisheries legislation should be enacted and to propose an expansion plan for the fishing industry. He must have had formal training in Marine Biology with relevant experience in research activities. Emoluments quoted above include a variable tax free overseas allowance of £660-1,410.

FISHERIES OFFICER
£3,500-5,585/West Cameroon

To supervise jointly with Oxfam and the US Peace Corps the development of inland fish culture. He must have a degree in Natural Science with considerable experience in tropical inland fisheries. Emoluments quotes above include a variable tax free overseas allowance of £1,000-2,085.

FISHERIES TRAINING OFFICER
£2,686-3,354/Zambia

To lecture to students taking a Diploma in Fisheries. He must have a degree in Social Sciences with specialisation in fisheries biology or equivalent and relevant field experience in Africa. Emoluments quoted above include an inducement allowance, normally tax free, of £684-750. A gratuity, normally tax free, of 25% of total emoluments is also payable.

SENIOR FISHERIES OFFICER
£3,766/Zambia

To administer large staff and direct fisheries research programmes in the lakes and rivers of Zambia. He must have either a good honours degree in biology plus ten years experience, or a higher degree plus eight years experience. Experience in freshwater biological research necessary. Emoluments quoted above include an inducement allowance, normally tax free, of £780. A terminal gratuity, normally tax free, of 25% of total emoluments is also payable.

ASSISTANT CONSERVATORS OF FORESTS
£2,029-3,622/Sarawak

To undertake general forest administration. He must have a degree in Forestry; previous experience desirable. Emoluments quoted above include an inducement allowance of £804-1,303. A gratuity of approximately 20% of total emoluments is also payable.

MARKETING MANAGER
£3,766/Zambia

To organise and control the marketing of timber. He must have a degree in Commerce or Economics OR a Diploma of the Institute of Marketing or Management with at least 5 years relevant experience. Emoluments quoted above include an inducement allowance, normally tax free, of £780. A gratuity, normally tax free, of 25% of total emoluments is also payable.

ASSISTANT CONSERVATOR OF FORESTS
£1,666-2,556/Guyana

Required for general forestry duties. He must have a degree in forestry, preferably with previous experience. Emoluments quoted above include an inducement allowance, normally tax free, of £636-936. A gratuity of 25% of total emoluments is also payable.

BIOLOGISTS
£1,734-3,354/Zambia

To control anti-tsetse field operations in an assigned area, including administrative duties and scientific assessment of tsetse control measures. They must have an honours degree in a natural science or a relevant applied science in agriculture and forestry, preferably with previous experience of tsetse control. Emoluments quoted above include an inducement allowance, normally tax free, of £600-750. A gratuity, normally tax free of 25% of total emoluments is also payable.

ASSISTANT CONSERVATORS OF FORESTS
£1,734-3,354/Zambia

For general district duties; or forest surveys and the preparation of working plans; or silvicultural research. They must have a degree in forestry. Emoluments quoted above include an inducement allowance, normally tax free, of £600-750. A gratuity, normally tax free, of 25% of total emoluments is also payable.

MINISTRY OF OVERSEAS DEVELOPMENT

Further information about any of these vacancies may be obtained by writing briefly, stating your age, qualifications and experience, to:

The Appointments Officer, Room 301 N,
MINISTRY OF OVERSEAS DEVELOPMENT,
Eland House, Stag Place, London, S.W.1.

(2487)

Nutritionist

FOOD STANDARDS AND SCIENCE DIVISION

Ministry of Agriculture, Fisheries and Food, London

NUTRITIONIST (graded Senior Scientific Officer) to take responsibility for nutritional aspects of the National Food Survey. These include identifying and investigating related nutritional problems, and planning and conducting collaborative investigations of the effects of modern methods of production and processing on the nutritive value of foods.

Qualifications : 1st or 2nd class honours degree or equivalent qualification in Biochemistry, Physiology or Nutrition and at least three years' postgraduate experience.

Salary : £2,318–£2,828.

Age : Normally 26–31.

Non-contributory pension. Prospects of promotion.

Application forms are obtainable by writing to the Civil Service Commission, Savile Row, London, W1X 2AA, or by telephoning 01-734 6010, ext. 229 (after 5.30 p.m. 01-734 6464 " Ansafone " service).

Please quote S/52-53/70/MAF/43/G. Closing date 14 July, 1970.

(2472)

STATES OF GUERNSEY HORTICULTURAL ADVISORY SERVICE

PLANT PATHOLOGIST

Applications are invited for the above post. Applicants must have a University Degree in a biological science and postgraduate experience in plant pathology.

The successful applicant will take charge of a small plant pathology section concerned primarily with the diagnosis of disease and pest problems in glasshouse crops, advising growers on control measures and, to a limited extent, evaluating new chemicals in field trials.

The salary scale will be on a scale £1,660—£2,760 which is reviewed annually in August each year. Commencing salary will depend on age, qualifications and experience.

Consideration will be given to applicants' housing requirements. Removal expenses and fares are normally paid.

Application form and further details are available from the **Establishments Officer, Civil Service Board, Grange House, St. Peter Port, Guernsey.** Completed applications must be submitted not later than July 4, 1970.

(2489)

CITY OF YORK

APPOINTMENT OF KEEPER OF THE YORKSHIRE MUSEUM

(Salary : Senior Officers' Grade £1,870–£2,445)

Applications are invited for appointment as Keeper of the Yorkshire Museum, York, which houses valuable archaeological, geological and natural history collections.

Applicants should have a degree in archaeology, biology, geology or art history and preferably the Diploma of the Museums Association. Appropriate museum experience is essential.

Further information about the appointment from the Town Clerk, Guildhall, York, YO1 1QN, to whom applications should be sent by July 8, 1970. (2492)

UNIVERSITY OF WAIKATO

HAMILTON, NEW ZEALAND

SENIOR LECTURESHIPS AND LECTURESHIPS IN THE SCHOOL OF SCIENCE

The University of Waikato invites applications for Senior Lectureships and Lectureships in its new School of Science. Appointments to each position will be considered at either level, but not all appointments can be made at the Senior Lecturer level. The positions are as follows :

PHYSICAL CHEMIST, preferably with a teaching interest in thermodynamics and/or statistical mechanics.

PHYSICISTS with research interests in one of the following : the physics of the liquid state, geophysics, biophysics.

EARTH SCIENTIST to lecture in general geology including petrology, mineralogy and stratigraphy. Earth Sciences is planned to embrace studies dealing more particularly with the surface of the earth and at present includes courses in pedology, geology and geomorphology.

BIOLOGICAL SCIENTISTS with teaching and research interests in the following fields : plant physiology, animal physiology, genetics, population ecology.

Enquiries are invited in other fields about appointments which may be made in 1971 and 1972, with particular reference to the following fields : biochemistry, organic/biochemistry, microbiology, soil chemistry, geophysics and biophysics.

The University of Waikato started teaching Science in 1970 and has 130 first year science students and 14 D.Phil. students. Second and fourth year courses will be introduced in 1971 and third year courses in 1972.

The policy of the School of Science is to encourage inter-disciplinary research projects and research on problems of local interest.

As well as the School of Science, the University has Schools of Humanities, Social Sciences, and Education. Some science courses are available to students in these Schools. The University occupies a pleasant site of about 130 acres in the city of Hamilton.

Salary scales are under review. At present, salaries are as follows :

Senior Lecturers : $NZ4,700-$NZ5,500-$NZ6,600.

Lecturers : $NZ3,100-$NZ4,800.

Conditions of appointment are available from the Registrar of any university in New Zealand and from the Secretary of the Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, WC1H OPF.

Applications close on July 20, 1970.

(2480)

UNIVERSITY OF DURHAM

DEPARTMENT OF PSYCHOLOGY

Applications are invited for the post of COMPUTER SUPERVISOR in the Department of Psychology from October 1, 1970, or such later date as may be arranged. The person appointed will be responsible for the management of the Department's IBM 1130 on-line computing system and the preparation of programmes.

Candidates should be of graduate or equivalent standing and have experience of computer room practice and programming. Salary will be on the scale: £1,355 by £125 to £2,605 per annum with F.S.S.U., according to experience and qualifications.

Applications (3 copies) together with the names and addresses of three referees, should be sent by Monday, July 6, 1970, to the Registrar and Secretary, Old Shire Hall, Durham, from whom further particulars may be obtained. (2452)
